Values show mean ± standard deviation.
AoED = aortic root at end-diastole; BSA = body surface area; LAED = left atrium at end-diastole; LVDd = left ventricular end-diastolic dimension; LVDs = left ventricular end-systolic dimension; LVPWED = left ventricular posterior wall at end-diastole; LVSED = interventricular septum at end-diastole; NS = not significant; SVI = stroke volume index.

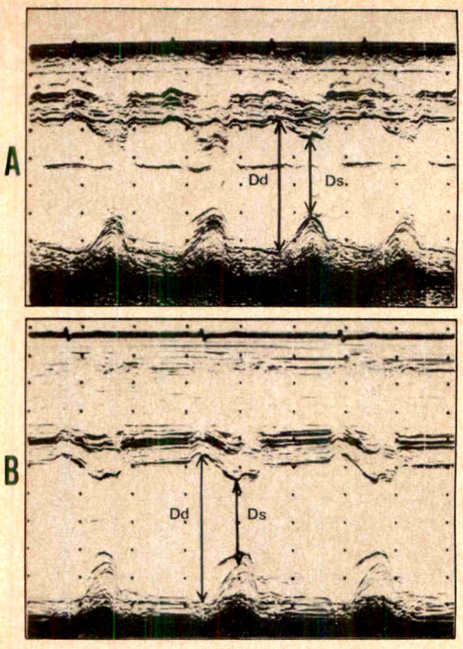

FIGURE 1. Echocardiogram of a healthy man (**A**) and of a patient with vibration disease (**B**). The ejection fraction in **A** was 77% with a left ventricular end-diastolic dimension (Dd) of 46 mm and a left end-systolic dimension (Ds) of 28 mm. The ejection fraction in **B** was 83% with a Dd of 52 mm and a Ds of 29 mm.

of the autonomic function was determined by digital plethysmography with auditory stimuli. The methods and procedures have been described in other reports.[5,6]

To avoid interobserver error, all measurements were made by the same observer and the values were obtained by the mean of 3 consecutive beats. The significance of differences between the means was determined using Student's t test.

Results

Left ventricular ejection fraction and stroke volume: Left ventricular ejection fraction (EF) was significantly higher in patients with vibration disease than in the control subjects. The EF in patients with vibration disease was 79 ± 4% (mean ± SD), ranging from 70 to 86%. In contrast, the EF of the control subjects was 75 ± 6%, a statistically significant difference ($p < 0.01$) (Table I). Left ventricular end-diastolic dimension indexes (LVDd/body surface area [BSA]) of patients with vibration disease and control subjects were 3.11 ± 0.28 cm/m^2 and 2.77 ± 0.27 cm/m^2, respectively. This difference also was statistically significant ($p < 0.001$). Left ventricular end-systolic dimension indexes (LVDs/BSA) of patients with vibration disease and the control subjects were 1.85 ± 0.19 cm/m^2 and 1.74 ± 0.22 cm/m^2, respectively. This difference was statistically significant ($p < 0.05$). The stroke volume index was also significantly higher in patients with vibration disease ($p < 0.001$). Several other echocardiographic measurements, ventricular septum at end-diastole, left ventricular wall at end-diastole, left atrium at end-diastole, and aortic root at end-diastole, were greater in patients with vibration disease than in the control subjects.

Figure 1 illustrates typical echocardiograms from a control man and from a patient with vibration disease. In the control group the EF was 77% with an LVDd of 46 mm and an LVDs of 28 mm. In the group with vibration disease the EF was 82% with an LVDd of 52 mm and an LVDs of 29 mm.

Correlation between left ventricular EF and autonomic nerve activity: Figure 2 illustrates the relation between left ventricular EF and autonomic nerve activity in patients with vibration disease. Autonomic nerve activity from digital plethysmography combined with auditory stimuli was classified into 3 types: normoreactive, hyperreactive, and hyporeactive.[5,6] The EF in the normoreactive, hyperreactive, and hyporeactive autonomic groups was 77 ± 6% (mean ± SD), 80 ± 3%, and 76 ± 2%, respectively. Thus, the EF tended to increase with increasing autonomic nerve activity. In contrast, all control subjects showed normoreactive activity.

Electrocardiographic findings: Table II illustrates the variables of the electrocardiogram. The amplitude of the T waves was analyzed as a ratio to the R waves. From analyses of limb lead I and precordial leads V_5 and V_6, only precordial lead V_6 was significantly greater in patients with vibration disease ($p < 0.05$). Flat T waves in limb leads or in precordial leads were observed in 1 patient with vibration disease and in 3 members of the control group. Using voltage criteria, left ventricular hypertrophy was noted in 5 patients with vibration disease. However, the control group was not indicative of left ventricular hypertrophy. From analyses of ventricular deflections, the sum of $R_I + S_{III}$ in patients with vibration disease was smaller than that in the control group, and the sum of $S_{V_1} + R_{V_5}$ was greater in patients with vibration disease than in the control group.

Resting heart rate in the group with vibration disease was significantly lower than that in the control group ($p < 0.001$). The former was 59 ± 8.1 beats/min, and the latter 67 ± 9.3 beats/min.

Values for blood pressure and the cardiothoracic ratio

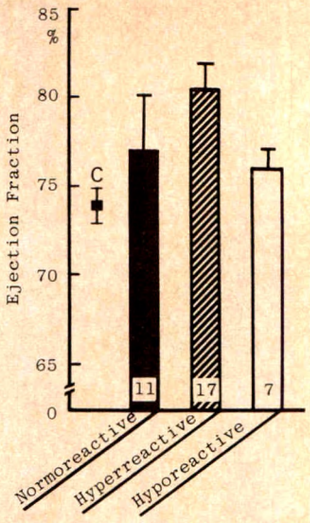

FIGURE 2. Correlation of left ventricular ejection fraction and autonomic nerve activity in patients with vibration disease. The autonomic tones were classified as normoreactive, hyperreactive, and hyporeactive with digital plethysmography combined with auditory stimuli. The ejection fraction (mean ± standard deviation) in the normoreactive (11 patients), hyperreactive (17 patients), and hyporeactive patients (7 patients) was 77 ± 6%, 80 ± 3%, and 76 ± 2%, respectively. Note that the ejection fraction increases with the activity of the autonomic nervous system. C indicates the ejection fraction (mean ± standard deviation) in the control subjects. All of them showed the normoreactive autonomic tones.

were within the normal range in both groups, and no significant differences were observed between the 2 groups.

Discussion

Defense mechanism in vibration disease: During the use of vibrating tools, the human body is exposed to 3 major stressors: vibration, noise, and cold. Typical levels of vibration are from 0.316 to 100 m/s^2 and of noise from 80 to 120 dB(air). These intensities can apparently stress the human body. The stressors may excite the hypothalamus and the limbic lobe in the cortex, in which the higher center of the autonomic nervous system exists. Consequently, the sympathetic tone could be significantly augmented. In these situations, defense mechanisms to the stressors may be provided in the human body, so that an adaptive response can be produced. Thus, habitual operation of vibrating tools may result in the development of mechanisms for adaptation to stress in the human body.

Increased left ventricular ejection fraction: A high incidence of bradycardia and cardiomegaly (cardiothoracic ratio >0.5) and a low incidence of hypertension have been observed in a study of 300 patients with vibration disease.[2] Also, endurance athletes possess resting sinus bradycardia, cardiomegaly, comparatively low blood pressure, increased cardiac output and left ventricular EF, and others.[7] In the present study, an increase was found in left ventricular EF and stroke volume. Left ventricular EF is commonly used as an index of left ventricular function. It is calculated by the

TABLE II Electrocardiographic Findings in Patients With Vibration Disease and Control Subjects

	Patients With Vibration Disease (n = 35)	Control Subjects (n = 35)	p Values
T/R wave ratio			
Lead I	0.399 ± 0.218	0.363 ± 0.206	NS
Lead V_5	0.267 ± 0.140	0.237 ± 0.075	NS
Lead V_6	0.315 ± 0.127	0.239 ± 0.112	0.05
Sum of R_I + S_{III} (mm)	6.1 ± 2.3	7.6 ± 4.2	NS
Sum of S_{V_1} + R_{V_5} (mm)	29.1 ± 9.2	28.0 ± 7.2	NS

NS = not significant.

left ventricular end-diastolic and end-systolic diameters. Echocardiographic study showed that endurance athletes had ventricular enlargement without thickening of the wall,[8] whereas other investigators found both an enlarged ventricular cavity and an increased wall thickness in professional cyclists,[9] basketball players,[10] and long-distance runners.[11] The present study showed a significantly enlarged ventricular cavity and an appreciably enlarged wall thickness. The difference in these findings may depend on the habitual level of physical activity, the type of sporting activity, and the athletes' performance level.[7]

Increased left ventricular EF and stroke volume at rest may be due to a latent cardiac reserve which is present in endurance athletes. These facts in endurance athletes are plausibly an adaptation to severe physical exercise; however, the mechanism responsible for this adaptation is unclear. The most frequently cited explanation involves alterations in the autonomic nervous system.[7]

Mechanism of adaptation: Habitual use of vibrating tools, that is, chronic exposure to vibration, noise, and cold, may produce autonomic imbalances that are related to the severity of vibration disease.[12] Approximately 75% of 300 cases of vibration disease showed autonomic imbalances.[2] In the present study, autonomic imbalances were observed in approximately two thirds of the patients. This is similar to the changes observed in endurance athletes.[7] The human body may adapt to the underlying conditions[4,7]; consequently, cardiovas-

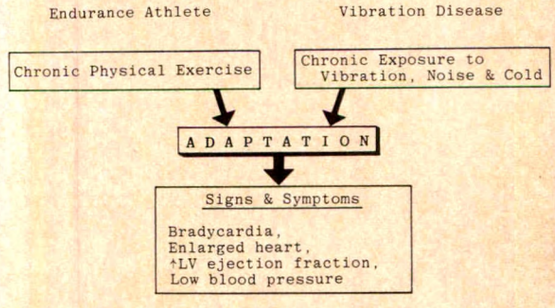

FIGURE 3. A hypothetical scheme illustrating the similarity of the adaptive responses of the cardiovascular system in an endurance athlete and in a patient with vibration disease. LV = left ventricular.

cular signs and symptoms such as bradycardia, enlarged heart, increased left ventricular EF, low blood pressure, and others appear (Fig. 3).

The amplitude of the electrocardiographic T waves, which was expressed as a ratio of the T wave to the R wave, was higher in the group with vibration disease than in the control group. The ratio in precordial lead V_6 was particularly greater than that in the control subjects. Other investigators have described a high amplitude of the T wave in the electrocardiogram of endurance athletes.[13,14] The mechanism of production of the high amplitude T wave is unclear; however the increased amplitude may be a reaction of the heart to stressors. Other findings in the present study generally agree with those of previous studies.[13,14]

Cardiovascular signs and symptoms in patients with vibration disease are relieved approximately 7 years after the use of vibrating tools is stopped.[15] Circumstantial evidence in the present study, such as the high incidence of increased autonomic tone, supports the concept that the cardiac reserve is maintained as an adaptation mechanism for many years.

In conclusion, the cardiovascular signs and symptoms in patients with vibration disease are similar to those frequently observed in endurance athletes. The signs and symptoms may be an adaptive response of the cardiovascular system. Finally, the clinical features in patients with vibration disease include adaptive responses to the stressors as well as direct injuries caused by vibration.

Inderal—a primary agent for the control of many arrhythmias.

INDERAL is effective in a broad range of arrhythmias. Consider INDERAL first for a variety of supraventricular arrhythmias. While ventricular arrhythmias do not respond as predictably as supraventricular arrhythmias, INDERAL is often considered as drug of first choice for ventricular arrhythmias induced by catecholamines or digitalis.

INDERAL is uniquely suited for long-term prophylaxis...it is an antiarrhythmic agent that offers a particularly favorable side effects profile*...and INDERAL is the only beta blocker indicated for the treatment of arrhythmias *and* coexisting angina and hypertension.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

Propranolol hydrochloride is contraindicated in 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. Propranolol acts selectively without abolishing the inotropic action of digitalis on the heart muscle (i.e., that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by propranolol's negative inotropic effect. The effects of propranolol and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during propranolol therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of propranolol therapy. Therefore, when discontinuance of propranolol is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when propranolol is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If propranolol therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute propranolol therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long-term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since propranolol is a competitive inhibitor of beta-receptor agonists, its effects can be reversed by administration of such agents, e.g., isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), propranolol should be administered with caution since it may bloc
chodilation produced by endogenous and exogenous catecholamine stimulation
receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta
adrenergic blocking activity, propranolol may prevent the appearance of premonit
and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is
important to keep in mind in patients with labile diabetes. Hypoglycemic attacks m
accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of propranolol in human pregnancy has not
established. Use of any drug in pregnancy or women of childbearing potential req
the possible risk to mother and/or fetus be weighed against the expected therape
fit. Embryotoxic effects have been seen in animal studies at doses about 10 times t
mum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine-depleting drugs such as reserpine should be cl
observed if propranolol is administered. The added catecholamine-blocking actio
drug may then produce an excessive reduction of the resting sympathetic nervou
Occasionally, the pharmacologic activity of propranolol may produce hypotension
marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotens

As with any new drug given over prolonged periods, laboratory parameters sho
observed at regular intervals. The drug should be used with caution in patients wit
renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block;
sion; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thron
nic purpura. *Central Nervous System:* lightheadedness; mental depression manife
insomnia, lassitude, weakness, fatigue; reversible mental depression progressing

Update your echo lab with Cardiac Doppler.

Sonacolor® CD

CARDIAC DOPPLER

The Cardiac Doppler system expands conventional echocardiography by providing noninvasive assessment of flow velocities through all four heart valves. It is all you need to confirm stenotic or regurgitant valvular disease.

- Color spectral patterns grade the degree of valve stenosis and turbulence.
- Valve cross-sectional areas can be derived from pressure gradient half-times.
- Color spectral patterns grade the degree of regurgitation. Valve prolapse is identified through the presence and timing of regurgitation.
- Detects the high velocity jets of flow through prosthetic valves. Detects prosthetic valve leak Monitors valve function over time.
- Color spectral patterns locate and grade shunt
- Displays ECG trace for time reference. Phono tr correlation of heart sounds with Doppler flow v patterns.
- Computes cardiac output approximation, stroke volume and average flow.

Writing with care for CHF:

Avoid any change in the classic digitalis-Lasix® regimen.

(BRAND OF furosemide)

9 out of 10 cardiologists specify LASIX® (furosemide) by brand name.* And 2 out of 3 take the extra step to prevent substitution.*

7 out of 10 cardiologists also specify the leading brand of digoxin.* Both are part of the classic LASIX®-digitalis regimen.

In the same survey,* LASIX® and the leading brand of digoxin were named more often than any other agent, in any therapeutic class, as drugs for which these cardiologists would *never* allow generic substitution. Both were prescribed by brand name more often than any other drug.

LASIX®—specified for good reason.

Especially in CHF, precision is crucial. Any therapeutic variable could easily upset the sensitive digitalis/diuretic/electrolyte balance and precipitate digitalis toxicity.

LASIX®, the most thoroughly documented drug in its class, offers quality so consistent that almost 8 billion tablets have been manufactured without a single product recall. In more dosage strengths and forms than any other diuretic. Good reason for the cardiologists surveyed to say they prescribe LASIX® more frequently than all other diuretic agents they named.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

*National survey of 2960 physicians, including 1502 cardiologists and other physicians subspecializing in cardiology, conducted by Hoechst-Roussel Pharmaceuticals Incorporated, Somerville, New Jersey. August, 1982.

Do Not Substitute

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, M.D., FACC, Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

Royal Postgraduate Medical School
(University of London)

at the Hammersmith Hospital

DIPLOMA COURSE IN CARDIOLOGY

A one-year course commencing in October 1983

This course is intended to provide intensive education, at post-graduate level, for approximately 15 students by formal lectures every morning and seminars every afternoon, with practical, individual training in diagnosis, new methodologies and therapy for groups of two to four students.

Clinical approach to adult and paediatric diseases. Electrocardiography, including stress testing and ambulatory monitoring.

- Phonocardiography and impluse cardiography
- Echocardiography • Intensive cardiac care
- Cardiac catheterisation and angiography
- Nuclear cardiology • Cardiac roentenology
- Pacemaking and clinical electrophysiology
- Cardiovascular pharmacology • Surgical aspects

Participation in Research Programmes is optional

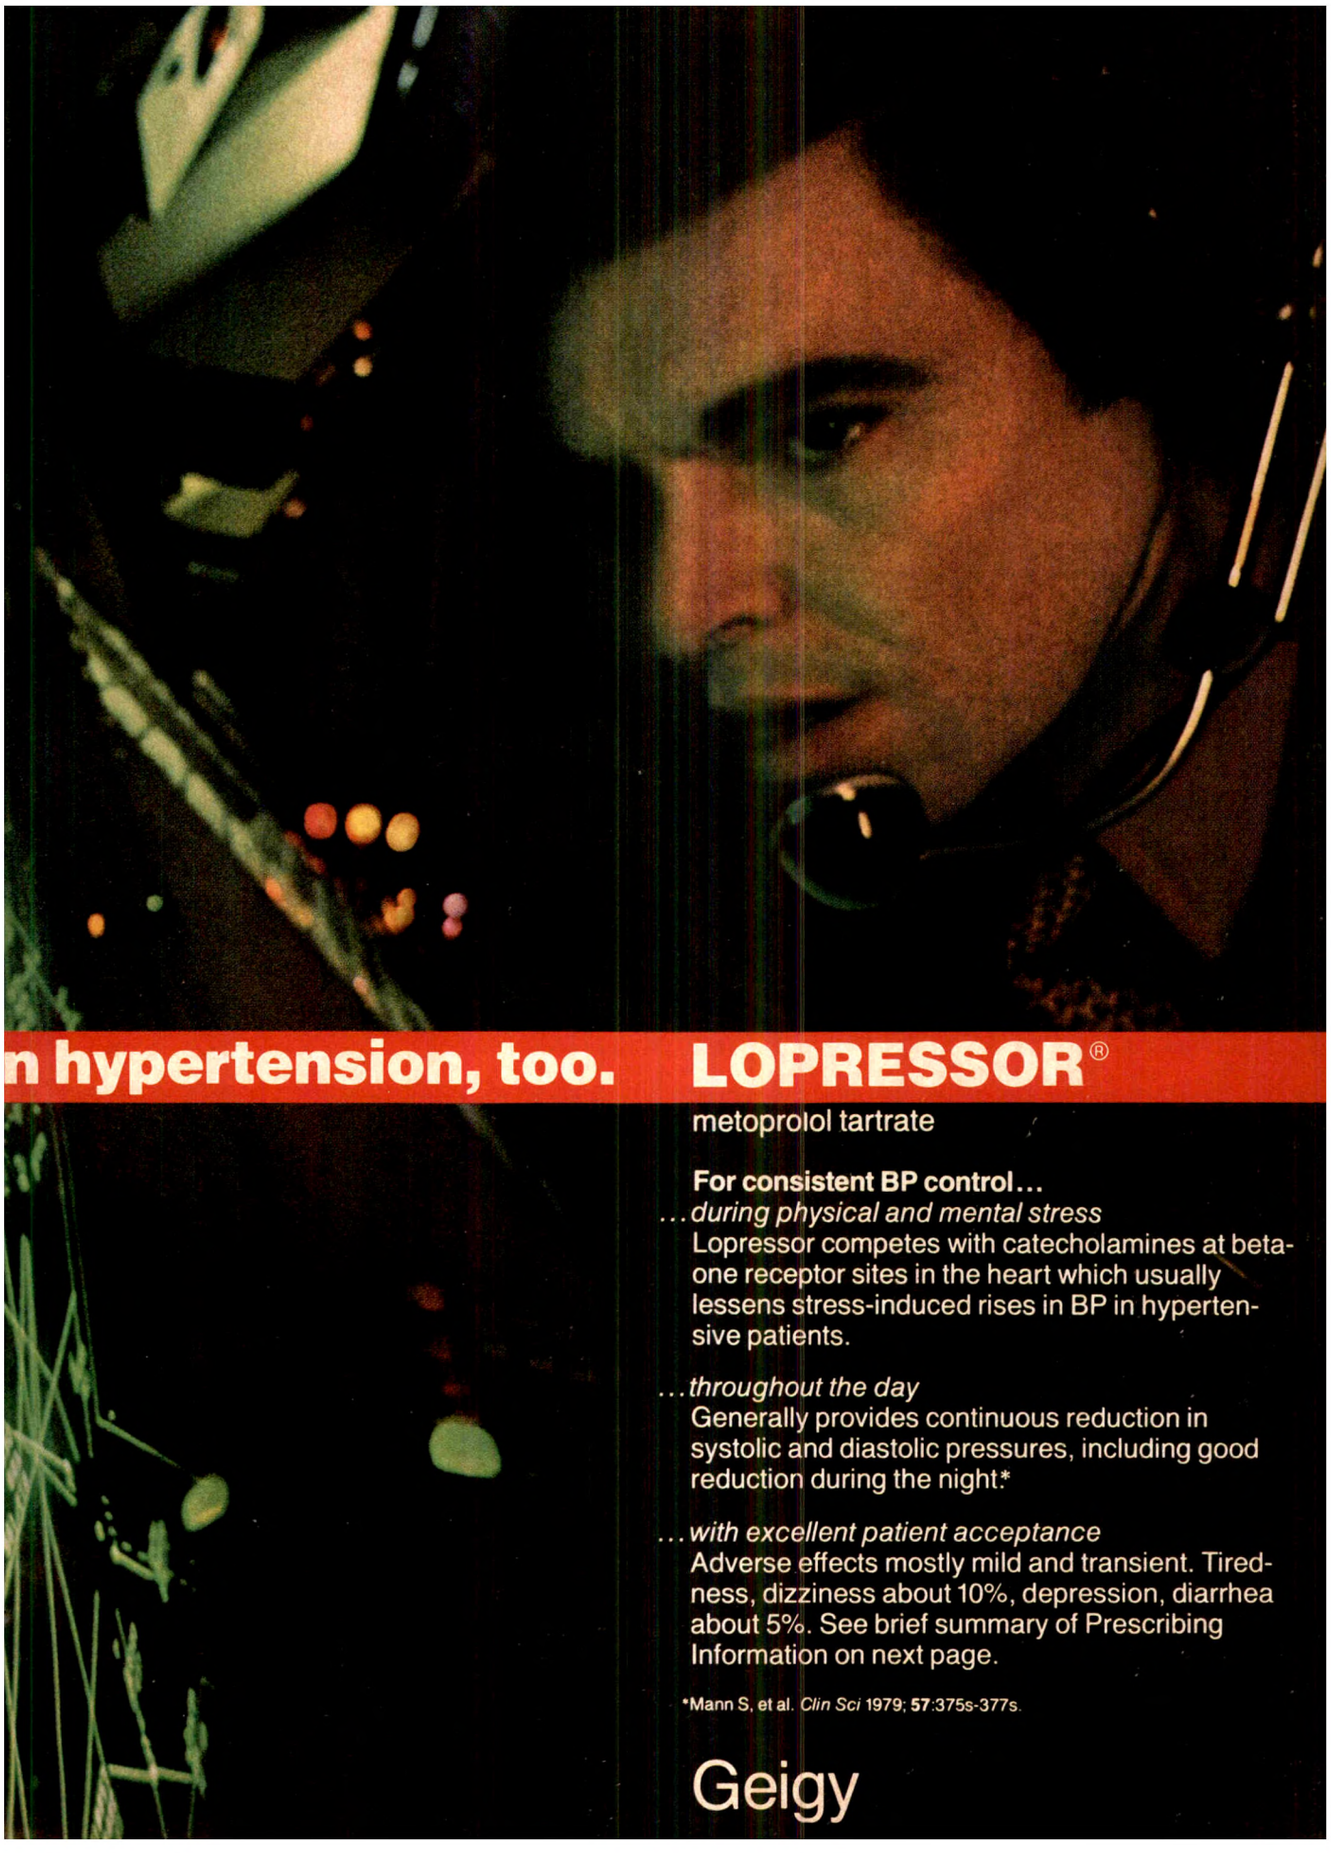
The course for the diploma is open to graduates in medicine who will have at least six months specialist practice in cardiology before starting the course.

Further details and information on fees are available from:

School Office
Royal Postgraduate Medical School
Du Cane Road, London W12 OHS

Tel: 01 743 2030 ext 351

Consistent control counts



n hypertension, too.

LOPRESSOR®

metoprolol tartrate

For consistent BP control...

...*during physical and mental stress*
Lopressor competes with catecholamines at beta-one receptor sites in the heart which usually lessens stress-induced rises in BP in hypertensive patients.

...*throughout the day*
Generally provides continuous reduction in systolic and diastolic pressures, including good reduction during the night.*

...*with excellent patient acceptance*
Adverse effects mostly mild and transient. Tiredness, dizziness about 10%, depression, diarrhea about 5%. See brief summary of Prescribing Information on next page.

*Mann S, et al. *Clin Sci* 1979; **57**:375s-377s.

Geigy

Lopressor®
metoprolol tartrate

An antihypertensive beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.
Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).
Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.
In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.
Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.
Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**
Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.
Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.
Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.
Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.
Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.
Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.
Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.
Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.
Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.
Usage in Children: Safety and effectiveness in children have not been established.
Adverse Reactions Most adverse effects have been mild and transient.
Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.
Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**
Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**
Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.
Allergic: Pruritus has occurred in less than 1 of 100 patients.
Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients. The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.
Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.
Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics
Cardiovascular: Intensification of AV block (see **Contraindications**).
Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura
Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.
Miscellaneous: Reversible alopecia.
Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.
Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.
This drug should be stored at controlled room temperature and protected from moisture.
How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.
Store at controlled room temperature and protect from moisture.
Dispense in tight, light-resistant container (USP).

Angiographic Demonstration of Coronary Occlusion During Spontaneous Acute Myocardial Infarction and Subsequent Angiographically Normal Coronary Arteries

Joseph Lindsay, Jr., MD
Sean Dwyer, MD
Usha Punja, MD

The occurrence of acute myocardial infarction (AMI) in a patient subsequently shown to have angiographically normal coronary arteries is at variance with classic concepts regarding the causal relation between AMI and coronary arterial occlusion. Temporary arterial occlusion by spasm[1,2] or thrombus[1,3,4] has been suggested in this circumstance, but no patient has been reported in whom such a sequence was demonstrated.

A 29-year-old previously healthy man was hospitalized for symptoms and electrocardiographic changes of AMI. Selective coronary arteriography peformed 5.5 hours after the onset of symptoms demonstrated occlusion of the proximal left anterior descending (LAD) artery (Fig. 1, top). Left ventriculography demonstrated marked anterior hypokinesia. The right and left circumflex coronary arteries were normal. Intracoronary nitroglycerin (300 μg) did not resolve the occluding lesion, but it was substantially smaller after the administration of 230,000 units intracoronary streptokinase (Fig. 1, center).

Intravenous nitroglycerin and oral nifedipine were begun; later, full-dose anticoagulation was administered. Serum creatine phosphokinase exceeded 2,000 units and included an MB fraction of 19%.

On the 17th hospital day, cardiac catheterization was repeated. Left ventricular end-diastolic pressure was 14 mm Hg. Left ventriculography demonstrated anterior hypokinesia and inferoapical dyskinesia. All major coronary arteries were widely patent (Fig. 1, bottom).

Congestive heart failure progressed thereafter. A cerebral embolism led to death 4 months after the AMI.

At necropsy the heart weighed 480 g, and all 4 cavities were dilated. A transmural scar involved the septal and anterolateral portions of the left ventricular wall, and foci of necrosis were present in the anterior wall. A thrombus overlay the area of fibrosis in the left ventricular apex. The coronary arteries were free of significant narrowing except for a localized 75% cross-sectional area narrowing of the proximal LAD artery by an atherosclerotic plaque (Fig. 2). An embolus was present in the right middle cerebral artery with a resulting cerebral infarct.

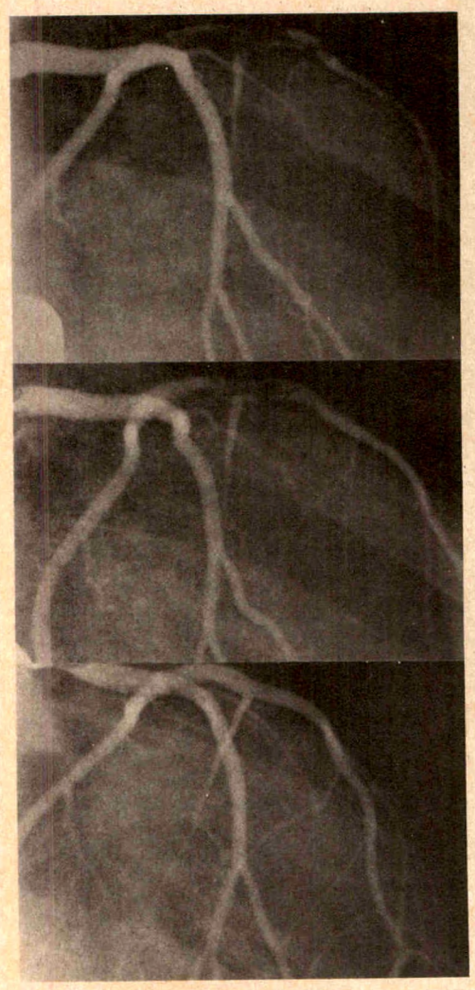

FIGURE 1. Coronary arteriographic views of the left coronary artery in the right anterior oblique projection. The **top panel** was filmed 5.5 hours after onset of AMI. It demonstrates a filling defect producing near-total occlusion of the proximal left anterior descending artery. The **center panel,** filmed after the administration of 230,000 units of streptokinase into the artery, shows striking reduction in the occluding lesion and restoration of distal flow. The **bottom panel,** filmed 17 days later, does not show a detectable lesion.

There are 2 extraordinary features of this case. First, we are aware of no other reports in which a major coronary artery was demonstrated to be nearly totally obstructed "early" after the spontaneous onset of AMI involving the distribution of that artery. On subsequent examination, significant obstruction could not be

From the Departments of Medicine and Pathology, Washington Hospital Center, and George Washington University, Washington, D.C. Manuscript received November 24, 1982; revised manuscript received December 16, 1982, accepted December 17, 1982.

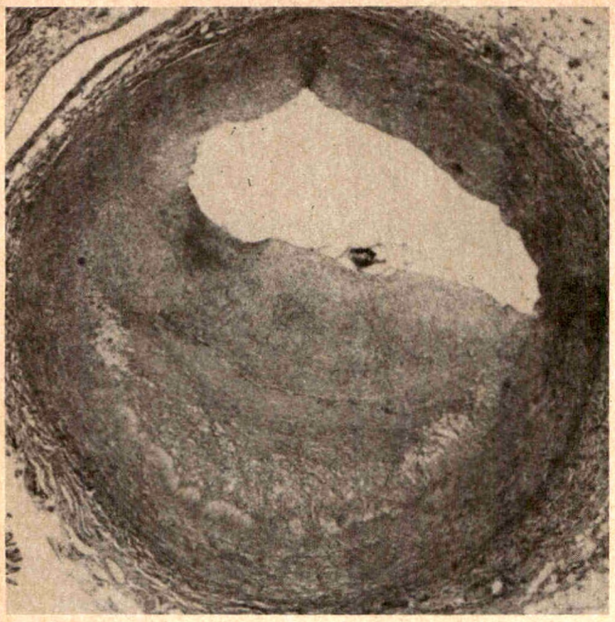

FIGURE 2. Photomicrograph of a cross-section of the proximal left anterior descending coronary artery 4 months after the AMI. (Hematoxylin and eosin stain; magnification ×30, reduced 4%.)

demonstrated either in that coronary artery or in any other. Second, necropsy 4 months after the "normal" arteriogram revealed a significant atherosclerotic lesion at the site of the occlusion demonstrated by angiogram at the time of the AMI (Fig. 2).

At least 2 explanations may be offered for this sequence. One, the coronary arteriograms failed to demonstrate a narrowing which in fact was present. Although it is well known that narrowing may be underestimated by angiography,[5,6] in this case the films were of high quality and in multiple projections, including hemiaxial views. Second, the arteries indeed were free of significant narrowing 4 months before necropsy.

Based on the angiographic appearance of the obstructing lesion in our case, it is reasonable to believe that thrombus plays a major role in the genesis of spontaneous AMI in some patients subsequently shown to have angiographically normal coronary arteries. The reason for clot formation is not clear. It appears reasonable to believe that the atherosclerotic lesion at the site of the previous angiographic obstruction was initiated by organization of the observed thrombus.

Transient Right Atrial Thrombus During Acute Myocardial Infarction: Diagnosis by Echocardiography

Patricia C. Come, MD

Echocardiographic diagnosis of right-sided cardiac thrombi is unusual. In the patient described herein, a large right atrial thrombus was detected after inferior myocardial infarction and was likely responsible for both systemic (paradoxical) and pulmonary emboli.

A previously healthy 62-year-old man had an acute inferior wall transmural myocardial infarction, complicated by first-degree heart block. Cardiac catheterization revealed akinesia of the left ventricular inferior wall and slight apical dyskinesia. The right coronary artery was totally occluded, and it failed to open after 250,000 units of intracoronary streptokinase. During catheterization, complete heart block developed and a temporay transvenous pacemaker was inserted into the right ventricle; it was removed 18 hours later.

The hospital course was complicated by pain (thought to represent pericarditis), short runs (5 to 6 beats in duration) of atrial fibrillation, and transient left facial weakness and numbness. A computerized tomographic scan of the head revealed no hemorrhage, and intravenous heparin was, therefore, begun. Echocardiography at that time (Day 10) revealed a large left ventricle with a hypokinetic ventricular septum and apex. No thrombus was visualized within the left side of the heart. A large mass of echoes was apparent within the right atrium attached to the lower lateral right atrial wall by a narrow stalk, which allowed it to prolapse through the tricuspid valve orifice into the right ventricle during diastole. In ventricular systole, in the apical and subxiphoid 4-chamber views, the right atrial mass appeared to push into the atrial septum at the presumed level of the foramen ovale, and in several frames a small part of the mass appeared to enter the left atrium by way of the atrial septum. Lung scan performed later that day demonstrated decreased perfusion, but normal ventilation in the superior segment of the right lower lobe and subsegmental defects elsewhere. By the next day, 2-dimensional echocardiography documented disappearance of the right atrial mass. A repeat lung scan documented the new appearance of decreased perfusion in the left upper and lower lobes compatible with significant recurrent pulmonary emboli. The patient was discharged re-

From the Charles A. Dana Research Institute and the Harvard-Thorndike Laboratory of the Beth Israel Hospital, Department of Medicine, Beth Israel Hospital, and Harvard Medical School, Boston, Massachusetts.
Manuscript received December 3, 1982; revised manuscript received December 21, 1982, accepted December 22, 1982.

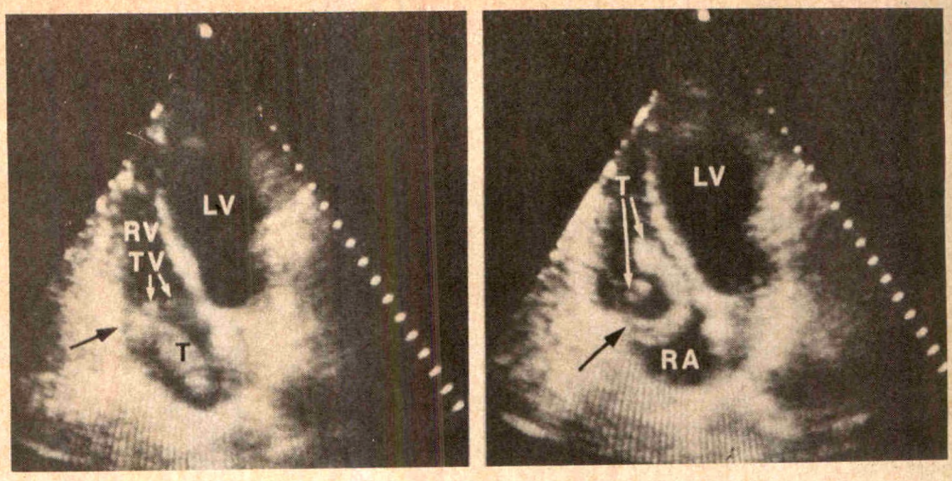

FIGURE 1. Two-dimensional echocardiograms performed with a Hoffrel mechanical sector scanner. Apical 4-chamber views in systole (**left panel**) and diastole (**right panel**) demonstrate the large thrombus (T) attached to the lower lateral wall of the right atrium (RA). LV = left ventricle; RV = right ventricle; TV = tricuspid valve.

ceiving warfarin and digitalis on the 19th hospital day. Out-patient echocardiography 5 months after the myocardial infarction demonstrated no recurrence of the right atrial mass.

To my knowledge, right atrial thrombi have not previously been documented by ultrasound in a patient with acute myocardial infarction. In my patient, it is likely that endothelial damage resulting from the right-sided cardiac catheterization or the subsequent placement and transient presence of a transvenous electrode for temporary pacing provided a nidus for thrombus formation. The short runs of atrial fibrillation in this patient, lasting only 5 to 6 beats at maximum, were likely of too short a duration to produce sufficient stasis for clot formation. The presence of such an unusual complication of both acute myocardial infarction and right-sided cardiac catheterization raises the possibility that streptokinase administration may in some way have permitted thrombus formation. Experience with this patient raises the question of whether patients should be anticoagulated after streptokinase administration, irrespective of achievement of clot lysis.

Extravascular Obstruction of the Superior Vena Cava by Hematoma After Open-Heart Surgery and Diagnosis by Scintigraphy

Mason H. Weiss, MD
Timothy M. Bateman, MD
Robert M. Kass, MD
David E. Brown, CNMT
Daniel S. Berman, MD
Richard J. Gray, MD

Although the superior vena cana (SVC) syndrome has been well studied,[1] its acute occurrence complicating adult open-heart surgery has not been reported. In this setting, the possibility of SVC tamponade due to pericardial hemorrhage and ensuing clot formation must be considered. Postoperative monitoring with an indwelling pulmonary artery balloon flotation catheter can cause acute thrombotic obstruction of the SVC.[2,3] Etiologic distinction is important since the management of extravascular compression is surgical and that of thrombotic obstruction is usually medical. In the latter situation, manipulation of the catheter before the application of thrombotic dissolution therapy could contribute to an adverse outcome.[4] We recently observed SVC syndrome early after open-heart surgery in a patient in whom a balloon flotation catheter was in place. Roentgenographic and scintigraphic findings were important in making the etiologic diagnosis, and hence, in choosing the appropriate therapy.

A 56-year-old woman underwent open-heart surgery because of dysfunction of a Harken prosthesis 12 years after mitral valve replacement. At surgery, dense adhesions from the previous operation were encountered. Replacement of the Harken prosthesis with a St. Jude valve, however, was uneventful. Postoperatively, the patient had a low cardiac index with poor urinary output; 24 hours after surgery, she had marked jugular venous distention without pulsations. Her face, arms, and upper torso had a peculiar bluish discoloration. Right atrial, pulmonary arterial, and pulmonary capillary wedge pressures were slightly elevated, and did not respond to volume challenge. Chest roentgenograms (Fig. 1) then showed that the right cardiac silhouette was particularly prominent. Technetium-99m equilibrium blood pool scintigraphy (Fig. 2) yielded an image, obtained 15 minutes after injection, of nearly absent radioactivity bordering the right heart base, including the region where the right atrium would normally be seen. An unusual and irregular concen-

From the Division of Cardiology, Department of Medicine, and the Department of Thoracic and Cardiovascular Surgery, Cedars-Sinai Medical Center, and the Department of Medicine, UCLA School of Medicine, Los Angeles, California. Manuscript received December 7, 1982; revised manuscript received December 24, 1982, accepted January 4, 1983.

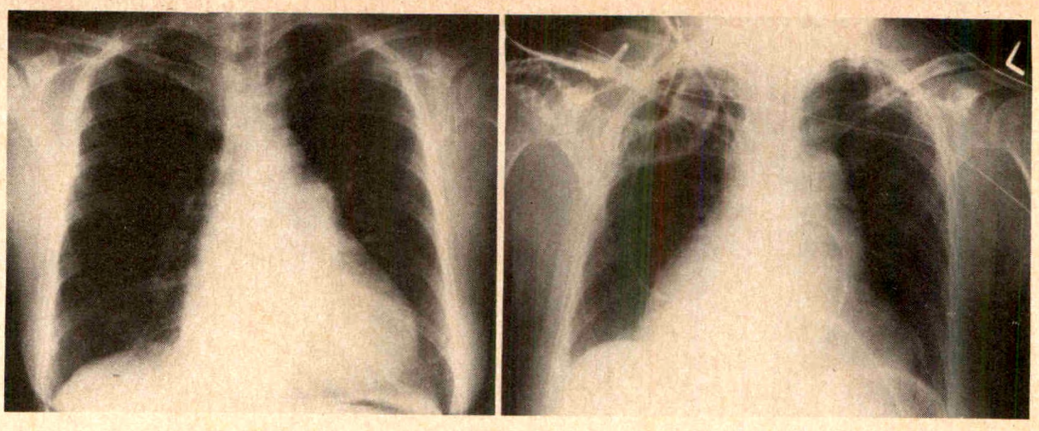

FIGURE 1. Chest x-rays performed immediately preoperatively (**left**) and 24 hours postoperatively (**right**). Marked prominence of the right heart border had developed.

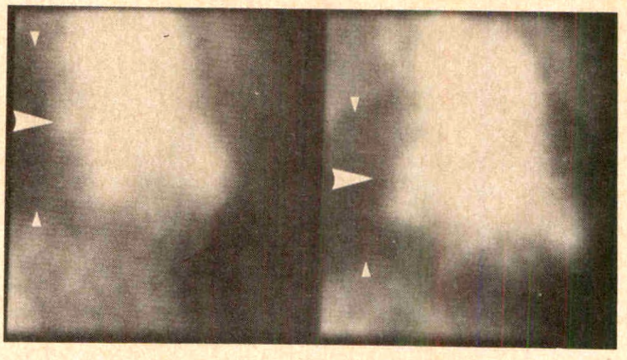

FIGURE 2. Scintigraphic images, anterior position, end-diastolic frames. Fifteen minutes after injection (**left**), there was a small, irregular accumulation of radioactivity (**horizontal arrow**) in a region above the expected position of the right atrium. In addition, there was a large area of absent radioactivity along the right side of the heart (outlined by **vertical arrows** in both images) and in the expected position of the right atrium, probably representing blood and blood clots present from before injection of the labeled red blood cells. One hour after injection (**right**), there was a much larger, more irregular, and immobile accumulation of radioactivity in this area (**horizontal arrow**), indicating the presence of active bleeding.

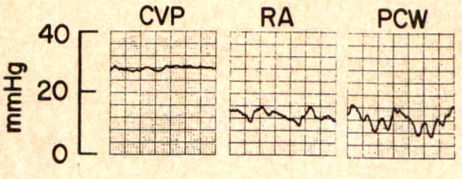

FIGURE 3. Sequential pressure tracings from the tip of pulmonary artery balloon flotation catheter, as it is advanced through the superior vena cava and the right atrium (RA), and into the pulmonary capillary wedge (PCW) position. CVP = central venous pressure.

tration of radioactivity was arising from a site cephalad to the expected position of the right atrium. Repeat imaging 1 hour after injection revealed a marked and immobile expansion of this irregular accumulation of radioactivity in the region of the base of the right side of the heart (Fig. 2). The balloon flotation catheter was withdrawn to the level of the internal jugular vein sheath, and reinserted with continuous monitoring of pressures. The tracings disclosed a markedly elevated, dampened-appearing SVC pressure, with relatively normal right atrial and pulmonary capillary wedge pressures (Fig. 3). The patient was returned to the operating theater, where about 500 ml of freshly clotted blood was found lying alongside and compressing the upper aspect of the right atrium, extending up to and including the SVC at its junction with the right atrium. When this blood was evacuated, the pressure in the SVC dropped markedly. A small arterial bleeding point was noted in the lysed adhesions surrounding the right atrium.

Cardiac tamponade is a common complication of adult open-heart surgery. Occasionally, the tamponade is localized to a single cardiac chamber. Right atrial tamponade may be suspected from comparative right atrial, right ventricular, and pulmonary capillary wedge pressures.[5] Hemorrhagic compression of the SVC may be regarded as a variant of right atrial tamponade, in that the cause is identical but the compression occurs at a higher level. Diagnosis will depend on physical examination if the right atrial pressure port of the pulmonary artery balloon flotation catheter is below the level of obstruction. Chest roentgenography and technetium-99m red blood cell scintigraphy may establish the hemorrhagic cause.[5,6]

Amiodarone Therapy During Pregnancy

William J. McKenna, MD
Louise Harris, MB, MRCP
Edward Rowland, MB
Andrew Whitelaw, MD, MRCP
Gerald Storey, BSc
David Holt, PhD

Amiodarone is a benzofuran derivative which contains 39% iodine by weight. Recently, the presence of a metabolite, desethyl amiodarone, has been noted in the plasma of patients receiving the drug on a long-term basis.[1] The drug is an effective agent for the treatment of refractory ventricular and supraventricular arrhythmias.[2] Its use during pregnancy has been limited by insufficient knowledge of maternal-fetal transfer and the documented adverse effects of excessive iodine.[3,4] Herein, we assess the maternal-fetal transfer of amiodarone and its desethyl metabolite in a patient who required this agent for prevention of life-threatening arrhythmia during pregnancy.

A 27-year-old woman was well and asymptomatic until her first pregnancy; during the last stage of delivery she had atrial fibrillation with a mean ventricular rate of 310 beats/min. This was successfully treated with direct-current cardioversion. The subsequent electrocardiogram and electrophysiologic studies showed the Wolff-Parkinson-White syndrome, type A (Fig. 1). Reentry atrioventricular tachycardia was initiated but promptly degenerated into atrial fibrillation which was conducted by way of the accessory pathway with a mean and shortest R-R interval of 220 and 170 ms, respectively. After intravenous ajmaline (50 mg followed by 30 mg), the ventricular rate slowed but atrial fibrillation persisted. Twenty minutes later, the patient converted spontaneously to sinus rhythm.

The patient refused prophylactic treatment because tachycardia had occurred only once and in association with the stress of childbirth. She was asymptomatic for 2 years, until the 16th week of her second pregnancy, when she had tachycardia that persisted for 2 hours. The patient was brought semiconscious to a local hospital where atrial flutter with a rapid ventricular response was documented; it terminated spontaneously. Treatment was started with quinidine sulfate, 300 mg 3 times daily. The patient was well until 34 weeks when she had another episode of sustained atrial flutter-atrial fibrillation (Fig. 1), which was terminated by direct-current cardioversion (10 J). Quinidine was then stopped and amiodarone started with a loading dose of 800 mg daily for 1 week and a maintenance dose of 400 mg daily thereafter. There were no further episodes and, after induction at 41 weeks, a healthy child was delivered without complication. The infant weighed 3,220 g and had an Apgar score of 9 at 1 minute. During the first 48 hours after birth and during labor, the infant's heart rate was 104 to 120

TABLE I Maternal and Infant Levels of Amiodarone and Desethyl Amiodarone

Sample	Time	Amiodarone (mg/liter)	Desethyl Amiodarone (mg/liter)
	Mother		
Plasma	8 days prepartum	1.7	1.3
Plasma	At delivery	1.5	1.4
Cord blood	At delivery	0.2	0.4
Breast milk	9 days postpartum	3.6	1.3
Breast milk	11 days postpartum	14.4	5.3
Breast milk	13 days postpartum	13.3	5.7
	Infant		
Plasma	At birth	0.4	0.35
Plasma	2 days	0.4	0.3
Plasma	14 days	0.4	0.25

TABLE II Range of Amiodarone (A) and Desethyl Amiodarone (DA) Concentrations in Breast Milk, Plasma Levels in the Infant and Mother, and the Infant's Estimated Ingestion of A and DA

Weeks Postpartum	Sample	A (mg/liter)	DA (mg/liter)	Estimated Ingestion (mg/kg/day) (Infant)	
				A	DA
6	Breast milk	2.8–16.4	1.1–6.5	1.5	0.7
	Plasma (infant)	0.4	0.25		
9	Breast milk	3.7–14.6	1.2–5.7	1.4	0.5
	Plasma (mother)	1.6	1.5		
	Plasma (infant)	0.4	0.15		

beats/min (normal 120 to 160) and the systolic blood pressure was 66 mm Hg (normal for age). Perfusion was normal, he behaved normally, and there was no goiter or corneal abnormality. Thyroid and liver function test results were normal.

The concentration of amiodarone and its desethyl metabolite in plasma and other biologic fluids was measured using a specific high performance liquid chromatographic technique.[1] *The results from samples collected from the mother and infant up to 2 weeks after the birth are shown in Table I. The infant was breast-fed, and over the subsequent 9 weeks samples of milk were expressed and submitted for the measurement of amiodarone and its desethyl metabolite. Up to 7 samples were expressed over a 24-hour period; the results for 2 such days are shown in Table II. Using a standard table relating age and breast milk intake, the infant's estimated ingestion of amiodarone and desethyl amiodarone are also shown (Table II).*[5]

Atrial fibrillation complicating the Wolff-Parkinson-White syndrome is a potentially lethal arrhythmia. When it occurs during pregnancy, there is a risk to the fetus from the associated hemodynamic changes and from the antiarrhythmic treatment. The aims in prophylaxis are (1) to prevent atrial and ventricular extrasystoles which may initiate reentry tachycardia or atrial fibrillation, and (2) to impair accessory pathway conduction and thereby slow the ventricular response were atrial fibrillation to occur. Conventional agents (quinidine, disopyramide) may be successful in preventing atrial fibrillation, but they are usually less effective in suppressing very rapid (mean ventricular rate 300 beats/min) accessory pathway conduction; this was the case in our patient.

Our recent experience has shown that amiodarone will prevent paroxysmal atrial fibrillation and will adequately attenuate even very rapid accessory pathway conduction.[7] We were, however, loathe to use this agent early in pregnancy because of the theoretical risk to the fetus. Amiodarone, 200 mg, contains approximately 75 mg of iodine within its structure. The precise fate of this large amount of iodine is uncertain.[8] Iodine is known to be (1) transferred rapidly across the placenta even against a concentration gradient,[4] (2) concentrated in fetal thyroid from as early as 14 weeks, and (3) associated with neonatal goiter after as little as 12 mg of iodine is ingested.[9] The risk of such complications for the individual patient is unpredictable and a genetic predisposition to develop goiter has been suggested.[10] In addition, the use of amiodarone during pregnancy carries the possible risk of teratogenic effects on the fetus from the compound. Nevertheless, in our patient the necessity of controlling these life-threatening episodes outweighed the risks of using amiodarone.

The maternal plasma levels of amiodarone and the desethyl metabolite remained stable after the loading period and were consistent with a dose of 400 mg daily.[11] At birth, the neonatal levels were approximately 25% of the maternal levels, indicating limited placental transfer of at least the parent compound and probably the metabolite. This infant who was exposed to amiodarone only during the last month of fetal life and was healthy with normal thyroid and liver function at birth was, however, bradycardic, and this may have been a reflection of the electrophysiologic effects of the drug. Demonstration of maternal fetal transfer of amiodarone indicates that administration of this drug earlier in pregnancy would have resulted in more prolonged exposure.

There was a wide variation in the concentrations of amiodarone and desethyl amiodarone in breast milk throughout the day, emphasizing the need to collect multiple samples for an accurate measurement of drug ingestion, as noted for other drugs.[12] Concentrations of the parent compound in breast milk were higher than the metabolite, probably reflecting the greater lipid solubility of the former. The estimated ingestion of amiodarone by this breast-fed infant was equivalent to a low maintenance dose (for example, 100 mg daily for a 70 kg adult). This was reflected in the infant's plasma levels, which did not vary significantly during the period of our measurements. In addition, desethyl amiodarone, the pharmacologic action of which is not yet known, was also excreted in breast milk. Our data suggest that breast feeding while receiving amiodarone could expose the developing infant to significant doses of the drug and should be avoided.

High-Degree Atrioventricular Block After Radiation Therapy

Dean J. Kereiakes, MD
Fred Morady, MD
Thomas A. Ports, MD

With increasing application of megavoltage radiation therapy, radiation-induced heart disease has become a significant cause of morbidity in patients surviving neoplastic disease. The clinical manifestations of radiation heart disease may not be apparent for years after therapy and include pericardial effusion, acute pericarditis, constrictive pericarditis, "cardiomyopathy," coronary artery disease, and valvular regurgitation, in decreasing order of frequency. Disorders of the specialized conduction system have received little attention. We present a case of high degree atrioventricular (AV) block after radiation therapy.

A 26-year-old man presented in 1966 with bilateral axillary adenopathy and biopsy of an involved node was consistent with Hodgkin's disease (lymphocyte-predominant type). The patient received 4,000 rads of cobalt therapy in a mantle distribution over 22 treatment fractions, with the cardiac apex shielded. No chemotherapy was given. In January 1982, the patient began having syncopal episodes. An electrocardiogram demonstrated right bundle branch block (BBB) with first-degree atrioventricular (AV) block (Fig. 1a); 24-hour ambulatory electrocardiographic recordings were normal. On electrophysiologic study, the AV nodal conduction time was normal, the infranodal conduction time (H-V interval) was 65 ms (normal <55 ms), and there was an infranodal block during incremental right atrial pacing. No supraventricular or ventricular arrhythmias could be induced with programmed stimulation. Syncope occurred spontaneously in the hospital, and an electrocardiogram revealed high-degree AV block (Fig. 1b). There was no change in degree of AV block or in ventricular rate after the intravenous administration of 1.0 mg of atropine. Intravenous epinephrine increased the ventricular rate with return of consciousness. A permanent pacemaker was inserted.

Over the next 6 months, exertional dyspnea developed. Examination was consistent with constrictive pericarditis, which was confirmed by cardiac catheterization. Coronary angiography was normal. Pericardiectomy was followed by relief of dyspnea.

Complete AV block from tumor invasion of the conduction system has occurred with Hodgkin's lymphoma and other tumors; however, direct inspection of the heart and pericardium in the present case revealed no evidence of this. We believe that AV block and constrictive pericarditis in this patient were sequelae of previous mediastinal irradiation.

TABLE I Summary of Previous Reports of Radiation-Induced High-Degree AV Block

Report	Age (yr) at Treatment	Radiation Dose and Field	Chemo-therapy	Years to Onset of High-Degree AV Block	Associated Findings
Rubin et al[1]	44	"Massive"	0	23	Left BBB
Ali et al[2]	19	5,000 rads to heart	+	6	Right BBB, LAFB, pericarditis
Tzivoni et al[3]	32	6,000 rads parasternal	0	18	Second-degree AV block
	40	3,700 rads left thorax	0	23	Second-degree AV block
Cohen et al[4]	20	4,000 rads mantle	+	11	Pleuropericarditis
Patri and Patri[5]	68	4,600 rads left bronchus	0	1	Second-degree AV block

LAFB = left anterior fascicular block.

Conduction disorders reported after radiotherapy to the chest include right BBB, left BBB, right BBB and left anterior fascicular block, right BBB and left posterior fascicular block, and second- and third-degree AV block. Including the present case, there are 7 reports of high-degree AV block after radiation therapy[1–5] (Table I). All patients received ≥4,000 rads to the chest. The interval to development of high-degree AV block ranged from <1 to 23 years (median 14). Preexistent BBB, second-degree AV block, or pericardial disease was common. All patients had symptoms necessitating implantation of a permanent pacemaker. In 1 previous case, a His bundle electrogram demonstrated the level of AV block to be within the AV node.[4] In other cases, the level of AV block was not documented; however, surface electrocardiographic recordings suggested an equal frequency of AV nodal and infranodal block. In the present case, the lack of response to atropine during AV block suggests that the level of the block was infranodal. That the QRS morphology during high-degree AV block was identical to that present during periods of 1 to 1 AV conduction strongly suggests that the level of AV block was intra-Hisian.

High-degree AV block is a potential late complication of megavoltage radiation therapy to the chest. AV block may occur at or below the level of the AV node and usually requires pacemaker therapy. Associated radiation-induced cardiac abnormalities are common.

Amyloidosis Limited to Small Arteries Causing Angina Pectoris and Sudden Death

Jeffrey E. Saffitz, MD, PhD*
Kathleen Sazama, MD
William C. Roberts, MD

Amyloid deposits occur in 2 locations in body organs: *interstitium* and *blood vessels*. Of 54 patients with cardiac amyloid causing cardiac dysfunction studied in our laboratory, 53 (98%) had amyloid deposits involving both interstitium and blood vessels and 1 (2%) had amyloid deposits limited to blood vessels. Because only 2 other patients with amyloid limited to blood vessels have been reported, to our knowledge,[1,2] a brief summary of our case appears justified.

The patient was a 61-year-old woman who presented at age 56 years with inflamed eyelids, and work-up at that time disclosed the presence of immunoglobulin A (IgA)-myeloma. She received chemotherapy. At age 58 years (about 36 months before death), she developed chest pain diagnosed as angina pectoris and she was treated with isosorbide dinitrate and propranolol. She died suddenly at home.

Necropsy (SH#A81-47) disclosed amyloid deposits in blood vessels in virtually every body organ other than the brain without amyloid deposits in the interstitium of any body organ. The deposits involved the blood vessels in some organs—the heart, lungs, bowel, and skin—to a much greater extent than those in other organs. The deposits severely narrowed the lumens of many vessels but no organ infarcts occurred. The deposits were limited to the small intraorgan blood vessels (Fig. 1).

In the heart, amyloid was present not only in the intramural coronary arteries but also in the mural endocardium of all 4 chambers, particularly the atria, and in all 4 cardiac valves. (These structures may be considered modified

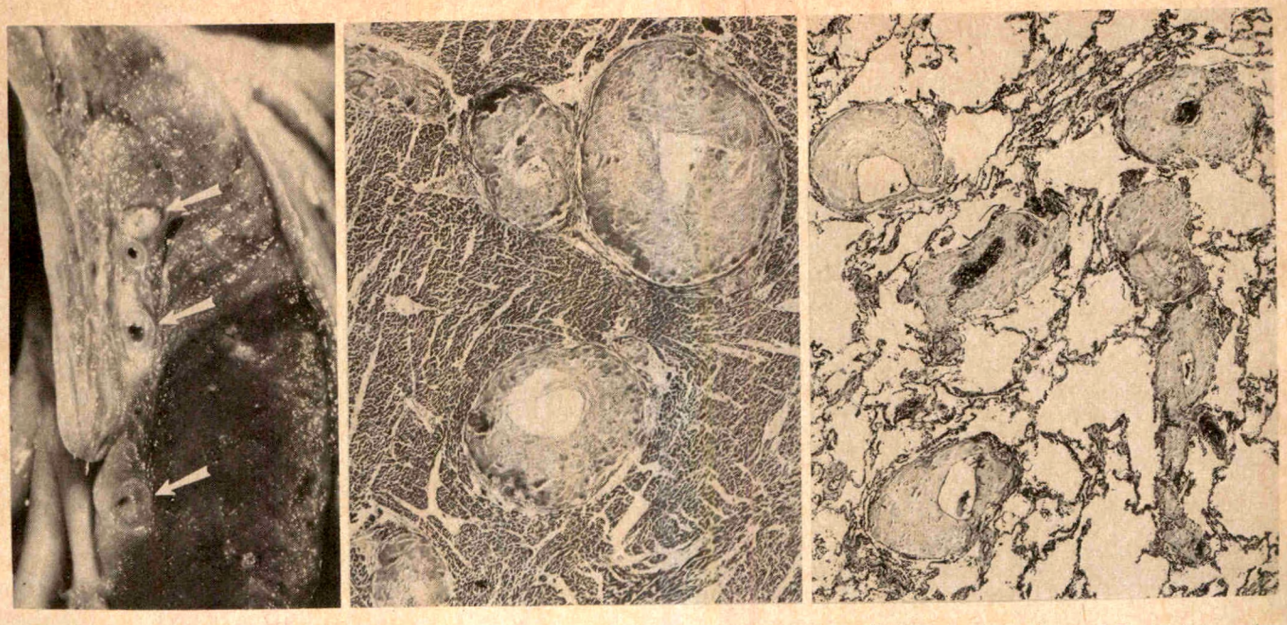

FIGURE 1. Longitudinal cut of ventricular septum (**left**) shows severe thickening of several intramural coronary arteries (**arrows**). Photomicrographs of left ventricular myocardium (**center**) and lung (**right**) reveal amyloid deposits in multiple arteries leading to luminal narrowing. No amyloid deposits are present in the interstitium. (Photographs by M.M.M. Moore.)

blood vessels because they are lined by endothelium.) In contrast, no deposits were located in the myocardial interstitium. The epicardial coronary arteries were free of significant narrowing and amyloid deposits.

Each of the 2 previously reported patients with amyloid confined to the vascular system also had angina pectoris without significant narrowing of the epicardial coronary arteries. Thus, amyloid confined to small (intramural) coronary arteries can cause angina pectoris and fatal cardiac arrest.

Anomalous Right Coronary Artery: A Surgically Correctable Cause of Angina Pectoris

Peter Bloomfield, MD
Conrad Erhlich, MD
Edward D. Folland, MD
Jesus A. Bianco, MD
Donald E. Tow, MD
Alfred F. Parisi, MD

Anomalous origin of the left coronary artery has been associated with sudden death in infancy and childhood and with clinically apparent ischemia in adult life.[1]

From the Cardiology Section and Nuclear Medicine Service, West Roxbury Veterans Administration Medical Center and the Department of Medicine, and Radiology, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts. Manuscript received November 17, 1982; revised manuscript received December 27, 1982, accepted January 4, 1983.

Anomalous aortic origin of the right coronary artery (RCA) has usually been regarded as an incidental finding.[2] Indeed, angina pectoris occurring in patients with such anomalous origin of the RCA has almost invariably been described in conjunction with significant coronary atherosclerosis. We here describe a patient with severe angina but free of significant atherosclerosis whose symptoms appeared to be caused by compression of an aberrant RCA between the aorta and right ventricular infundibulum.

A 65-year-old artisan developed angina pectoris at age 58 years (in 1974). Coronary angiography disclosed an aberrant origin of the RCA from the left main coronary artery (Fig. 1, top panels). The anomalous vessel was large and, like the left, free of all but minor atherosclerotic narrowing. The patient was treated with propranolol and nitrates and for 2 years his symptoms were well controlled. Then, over the next 3 years, the angina progressively worsened to the point that he was confined to a wheelchair and became totally dependent upon his wife for even basic needs such as bathing and dressing. Repeat catheterization disclosed normal intracardiac pressures and all 3 major coronary arteries were clearly free of any significant narrowings with the exception

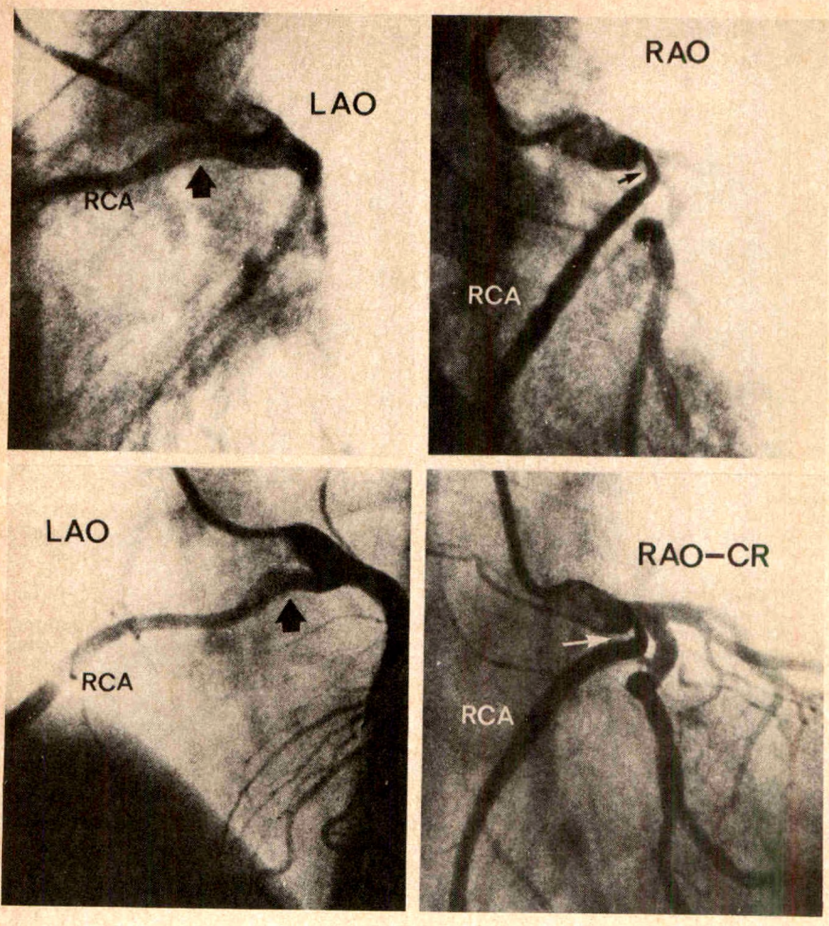

FIGURE 1. Coronary angiogram from the cardiac catheterization studies performed in 1975 (**top panels**) and 1981 (**bottom panels**). In the 1975 study, the **left panel** is a left anterior oblique (LAO) and the **right panel** a right anterior oblique (RAO) view. The right coronary artery (RCA) arises proximally from the left main coronary artery. On close inspection the proximal portion of the RCA appears smoothly narrowed (**arrow**) in the RAO view, but this segment is partly obscured by the vessels it overlies. In the LAO view the proximal segment of the RCA appears widened (**arrow**), but in this projection this segment is superimposed on the catheter. In the 1981 study (**bottom panels**), the **left panel** is also a perpendicular LAO view and the **right panel** a right anterior oblique view with cranial angulation (RAO-CR). In the RAO-CR view, the proximal segment of the RCA is clearly separated from the other vessels and shows a smooth and critical narrowing (**arrow**). In the perpendicular LAO view, this same proximal segment of the RCA is separated from the catheter and appears flattened and wider than the rest of the RCA (**arrow**). These 2 views therefore give the appearance of external compression of the proximal segment of the RCA as it passes between the 2 great vessels.

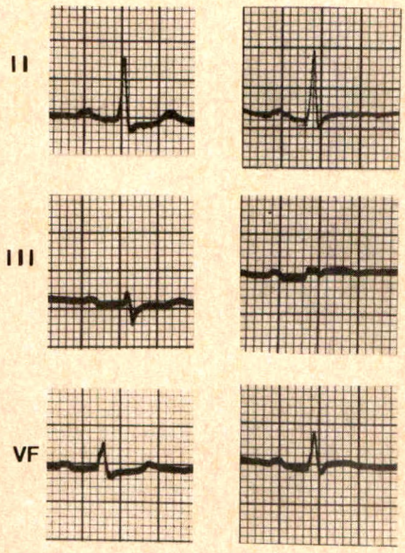

FIGURE 2. Electrocardiographic pacing study. **Left panel,** preoperative study. After pacing at 150 beats/min for 3 minutes, the patient had severe angina and 1 mm of S-T depression was seen in leads II, III, and aVF. **Right panel,** postoperative study. After pacing at 150 beats/min for 9 minutes without symptoms, no inferior S-T or T-wave changes appeared. Both tracings were taken immediately after cessation of pacing.

of a discrete segment of the anomalous RCA, which appeared critically narrowed where it passed between the aorta and right ventricular infundibulum. This segment was narrowed in the cranially angulated right anterior oblique view (a view not performed at the first catheterization) and widened in the perpendicular left anterior oblique view, giving the appearance of a "ribbon-like" external compression between the 2 great arteries (Fig. 1, bottom panels). The left ventriculogram was normal. On exercise, the patient developed severe angina within 30 seconds at a heart rate of 75 beats/min; S-T segment changes in the inferior leads were equivocal. When paced from the right atrium at 150 beats/min for 3 minutes, the patient had severe angina and 1 mm S-T segment depression in leads II, III, and aVF (Fig. 2, left panel). A thallium perfusion scan performed simultaneously showed hypoperfusion of the inferior wall which reperfused 3 hours later.

A single saphenous vein graft was placed to the RCA. Surgery was uneventful and the patient made a rapid recovery. His symptoms were totally relieved and he gradually resumed an active existence. Repeat pacing study 2 months after operation during which the patient was atrially paced at 150 beats/min for 9 minutes failed to produce symptoms or inferior electrocardiographic changes (Fig. 2, right panel) and the thallium perfusion scan was normal. He also completed 9 minutes of a standard Bruce exercise tolerance test without angina and without evidence of ischemia in the inferior leads.

In this case, a congenital anomaly of the RCA appears to be the cause of angina pectoris which first presented in middle age, followed a progressive and disabling course, and was completely relieved by coronary artery bypass surgery. A unique finding is the apparent external compression of the anomalous portion of the artery as it passes between the aorta and right ventricular infundibulum in the absence of any significant obstructive coronary atherosclerotic lesions. In an autopsy series of 10 patients with anomalous origin of the RCA from the left sinus of valsalva, Roberts et al[3] suggest that a possible mechanism of ischemia in these patients is the compression of the anomalous artery between the aorta and pulmonary trunk during exercise. We believe our case to be the first angiographic demonstration of such external compression of an anomalous RCA. This hypothesis is further supported by Liberthson's[2] demonstration of hypoplasia of the anomalous portion of an aberrant RCA at autopsy. The development of symptoms at age 59 in our case may be explained by progressive hypoplasia of the initial segment of the aberrant RCA or enlargement of the pulmonary trunk and aorta with age, or both.

Thus, anomalous RCA may be a rare cause of angina in middle-aged patients and results from compression of the anomalous artery between the great arteries. Multiple views in both oblique positions with hemiaxial angulation may be required at coronary angiography to demonstrate such external compression. Stress myocardial imaging with thallium-201 can be helpful in demonstrating hypoperfusion. Surgical bypass of the anomaly may relieve symptoms.

Bidirectional Blood Flow in Angiographically Normal Coronary Arteries

Paolo Esente, MD
Goffredo G. Gensini, MD
Alessandro Giambartolomei, MD
Deborah Bernstein, PhD

Bidirectional coronary flow is a frequent angiographic finding in patients with severe coronary artery stenosis[1] and after aortocoronary bypass.[2] Under normal physiologic conditions, although small coronary anastomotic channels do exist, they are functionally unimportant[3] and are not demonstrable by angiography.[4] We recently observed bidirectional flow in a patient without obstructive coronary disease.

A 56-year-old man underwent diagnostic cardiac catheterization and coronary angiography for evaluation of recent onset chest pain. Left bundle branch block had been present for years. Left ventricular and aortic pressures were normal and so was left ventricular function by angiography (Fig. 1). Selective coronary artery visualization ruled out obstructive disease and showed clear-cut evidence of bidirectional flow in the posterior descending branch of the right and in the distal circumflex branch of the left coronary artery (Fig. 2 and 3). There was obvious continuity between the distal segments of right and circumflex arteries with the most narrow point measuring about 1 mm in diameter (catheter tip used as a reference).

From Msgr. Toomey Cardiovascular Laboratory, St. Joseph's Hospital Health Center, Syracuse, New York.

Manuscript received January 1, 1983, accepted January 4, 1983.

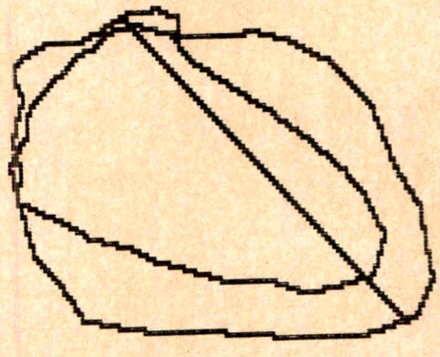

FIGURE 1. Computer-generated plot of the left ventricular end-systolic and end-diastolic contours, axis shifted.

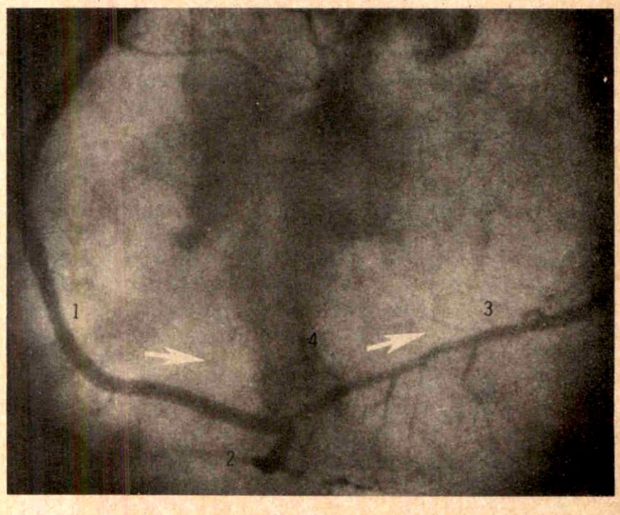

FIGURE 2. Right coronary injection in left anterior oblique projection. **Arrows** indicate the direction of blood flow. 1 = right coronary artery; 2 = posterior descending artery; 3 = distal circumflex artery; 4 = atrioventricular nodal branch.

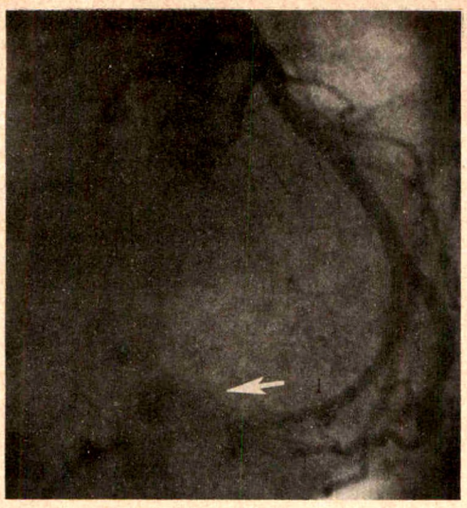

FIGURE 3. Left coronary injection in left anterior oblique projection. 1 = distal circumflex artery; 2 = atrioventricular nodal branch; 3 = posterior descending artery.

While the normal coronary circulation is functionally closed-ended, the pattern of the case presented is open-ended, similar to the circulation of the brain and extremities. We believe that this anomaly is of a congenital nature, since large anastomotic channels have been shown to regress once the situation causing their development is removed.[5] We also believe that bidirectional flow of this nature does not disturb the function of the coronary circulation, but rather would represent a potential "self-cure" for obstructive coronary disease.

Effect of Steroids on Postoperative Constrictive Pericarditis

Richard A. Ansinelli, MD
Kenneth D. Weeks, MD
Thomas S. Key, MD

Recently, constrictive pericarditis has become recognized as a complication of cardiac surgery in the absence of sepsis. Six cases had been reported before 1979.[1–4] In 1979, however, 13 additional cases were reported,[5–7] confirming that constrictive pericarditis is a rare but clinically important complication of cardiac surgery. Of the cases reported, all but 4 (2 diagnosed postmortem,[1–3] 2 managed medically[6]) have undergone pericardiectomy. This report documents 3 additional cases of pericardial constriction and suggests a mode of therapy that may eliminate the need for pericardiectomy.

Case Summaries

SH, a 15-year-old black girl, had reimplantation of an anomalous left coronary artery from the pulmonary artery to the aorta in April 1979. After surgery, postpericardiotomy syndrome developed with an effusion noted on echocardiography. Treatment with indomethicin and aspirin resolved the symptoms and signs within 2 weeks. Five weeks postoperatively, she had fatigue and chest pain atypical for angina. Physical examination disclosed jugular venous distention, Kussmaul's sign, and a loud pericardial knock. No pulsus paradoxus, friction rub, or edema were noted. Apexcardiography and phoncardiography (Fig. 1, left) revealed systolic retraction and a loud pericardial knock. Echocardiography showed paradoxical septal motion but no pericardial effusion. Right-sided cardiac catheterization revealed a diastolic plateau of 17 mm Hg and a typical "square-root" sign in the right ventricular pressure tracing. The patient was treated with prednisone, 10 mg twice daily, for 3 weeks. The dose was tapered over the subsequent 3 weeks. Symptoms resolved over 3 weeks, and repeat apexcardiography with phonocardiography in December 1979 showed no systolic retraction or pericardial knock (Fig. 1, right). Three years after surgery, there were no symptoms or signs of constriction.

EH, a 56-year-old black woman, underwent mitral valve replacement in October 1979 without complications. Four weeks after surgery, she had chest pain atypical for angina and dyspnea on exertion. Examination revealed hepato-

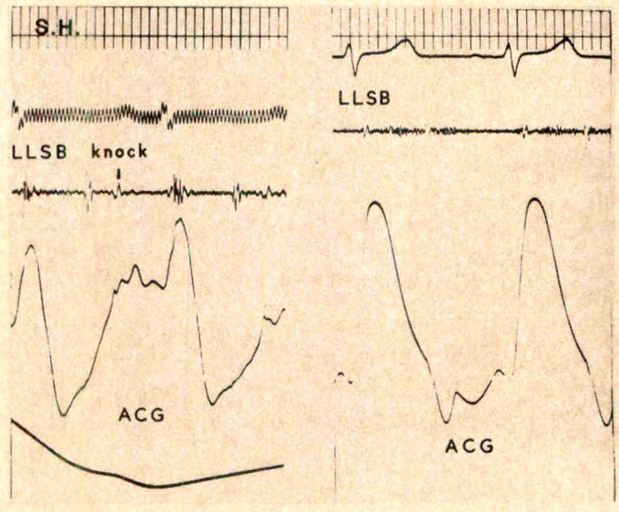

FIGURE 1. Patient SH. **Left,** before steroid therapy, a phonocardiogram showing a loud pericardial knock, and apexcardiogram (ACG) showing systolic retraction. **Right,** after steroid therapy, phonocardiograms showing no pericardial knock, and apexcardiogram showing normal contour. LLSB = lower left sternal border.

From the Cardiology Department, Walter Reed Army Medical Center, Washington, D.C. Manuscript received October 18, 1982; revised manuscript received December 21, 1982, accepted December 22, 1982.

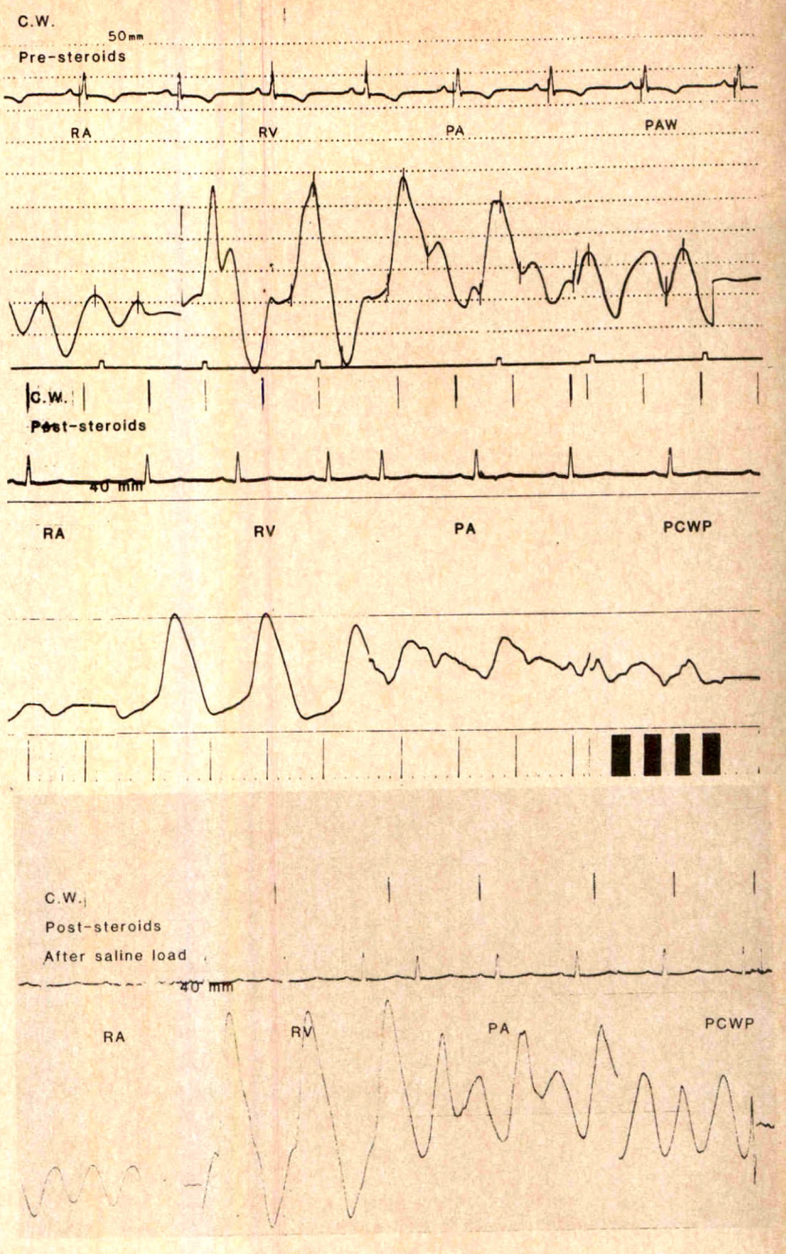

FIGURE 2. Patient CW. **Top,** before steroid therapy, pressure tracings show diastolic plateau and square-root sign. **Center,** after steroid therapy, absence of diastolic plateau and normal right ventricular pressure tracing. **Bottom,** after steroid therapy and saline loading, elevated pressures without contours suggestive of constriction. PA = pulmonary arterial pressure; PCWP = pulmonary arterial wedge pressure; RA = right atrial pressure; RV = right ventricular pressure.

megaly. No pulsus paradoxus, jugular venous distention, pericardial knock, or edema was present. Echocardiography showed a normal functioning mitral prosthesis and no pericardial effusion. Right-sided cardiac catheterization revealed a diastolic plateau of 22 mm Hg with a square-root sign in the right ventricular tracing. The patient was treated with prednisone, 60 mg daily, for 5 days, and then 30 mg daily for 2 weeks. The dose was then tapered over a 4-week period. Repeat right-sided cardiac catheterization 10 days after therapy was initiated showed normal pressures with resolution of the diastolic plateau and square root sign. Symptoms resolved after 2 weeks of therapy. Three years after surgery, there were no signs or symptoms of constriction.

CW, a 45-year-old white man, underwent 3-vessel coronary bypass grafting in August 1979. Surgery was complicated by the postpericardiotomy syndrome. An effusion was noted on echocardiography. Symptoms and effusion resolved with tapering steroid doses in the 2 weeks after surgery. Five weeks after surgery, he had fatigue, chest pain atypical for angina, dyspnea on exertion, and dizziness. Examination revealed jugular venous distention, Kussmaul's sign, a loud pericardial knock, hepatomegaly, and edema. No pulsus paradoxus or pericardial friction rub were present. Echocardiography showed paradoxical septal motion, but no pericardial effusion. Right-sided cardiac catheterization revealed a diastolic plateau with a square-root sign in the pressure tracing (Fig. 2, top). The patient was treated with prednisone, 20 mg twice daily, for 5 weeks. The dose was then tapered over a 4-week period with resolution of symptoms and signs. Recurrent angina led to cardiac catheterization in April 1982, which revealed normal right-sided pressures and contours (Fig. 2, center). After an infusion of 1,000 ml of normal saline solution over 8 minutes for evaluation of occult constriction,[8]

pressures increased, but showed no contours or plateau suggestive of constriction (Fig. 2, bottom). All grafts were patent, but there was progression of native disease, which is being managed medically. Three years after surgery there were no signs or symptoms of a constrictive process.

Discussion

Various causes of postoperative constrictive pericarditis have been proposed,[2,5,6] but no common factor has been identified. As pointed out by others,[3,6] it is probably a combination of factors that result in postoperative constrictive pericarditis. In 17 cases in which the pericardium has been examined at surgery[1,2,4–7] or necropsy,[1,3] most revealed a thick, fibrous adherent pericardium. However, in 1 case[5] there were several adhesions without obliteration of the pericardial space, and less scarring of the pericardium than in the other 2 patients. The investigators suggested that the spectrum of constrictive pericarditis may be broad, with fibrosis being the final stage.

Except for surgery, no therapy for constrictive pericarditis has been reported. Since our patients were stable and since inflammation is implicated in postoperative constrictive pericarditis, we considered a trial of high-dose corticosteroids to be a reasonable intervention. Our patients probably had an early form of a constricting process such as the surgical case just cited.[5] One would not expect a patient with a completed fibrous process to respond to steroids.

FUNCTIONAL CONSEQUENCES OF RIGHT CORONARY ARTERY ORIGINATING FROM LEFT SINUS OF VALSALVA

We read with interest the report by Roberts et al[1] dealing with the functional consequences of the right coronary artery (RCA) aberrantly originating from the left sinus of Valsalva. The authors' own data and those cited indicate that "origin of the RCA from the left sinus may produce cardiac dysfunction that can be fatal." The authors suggest that the mechanism of flow impairment in the aberrant RCA may be either the diminished flow consequent to the "slit like" origin of the aberrant ostium which becomes even more narrowed during exercise-induced dilatation of the pulmonary trunk and aorta, or the compression ("squeezing") of the anomalous RCA between the aorta and the pulmonary trunk.[2,3]

The latter possibility was challenged already by earlier investigators, mainly because such a phenomenon was never found during coronary arteriography[4–6] or in experimental models.[7] This hypothesis, however, seems to have had its proof in our recent demonstration in a patient of cyclic systolic compression of an aberrant RCA originating from the left sinus of Valsalva (Figure 1).[8] The decrease in the lumen of the RCA at its portion coursing between the great arteries during systole seems to give angiographic support to the theory of "squeezing." However, this finding does not exclude the presence of further mechanisms which may play an additional role in decreasing the flow in the aberrant vessel.

SENSITIVITY AND SPECIFICITY OF M-MODE ECHOCARDIOGRAPHIC SIGNS OF MITRAL VALVE PROLAPSE

The report by Haikal et al[1] makes an important contribution in reference to the incidence of different M-mode echocardiographic patterns associated with a nonejection systolic click. The goal of the study was to assign a discriminating statistical value to the sensitivity and specificity of those echocardiographic signs and patterns. At present, there is no uniform agreement on what constitutes a diagnostic standard for the identification of mitral valve prolapse (MVP). It is well known that some patients have a systolic click with or without a murmur, with no evidence of MVP on the echocardiogram. Therefore, any "diagnostic" finding that is being put on the testing bench of scientific analysis for validation needs to be compared and weighed against another standard. That is where the design of the study appears faulty. Sensitivity and specificity simply reflect the capability of detecting a true-positive or excluding a false-positive test result. To make such a statement about specificity or sensitivity, it is mandatory to be able to determine a true-positive test result with a significant degree of certainty. The group from Missouri used a hypothesis that is not universally proven, which is that a systolic click moving in the cardiac cycle with different maneuvers, with or without a murmur, represents or is equivalent to MVP. In the report by Haikal it is not mentioned whether 2-dimensional examination or angiography was performed or used for comparison purposes. The fact that the mid-systolic click was auscultated by 3 independent observers only ascertains the presence of such a finding but does not prove the coexistence of MVP. In that setting the specificity and sensitivity cannot be safely determined.

1. **Haikal M, Alpert MA, Whiting RB, Ahmad M, Kelly D.** Sensitivity and specificity of M-mode echocardiographic signs of mitral value prolapse. Am J Cardiol 1982;50:185–190.

REPLY: We agree that nonejection clicks are not specific for MVP. Indeed, such clicks have been described in patients with hypertrophic cardiomyopathy,[1] calcified right atrial myxoma,[2] ventricular septal defect with and without aneurysm of the ventricular septum,[3] and left-sided pneumothorax.[4] In each of these cases the systolic click was nonmobile. In contradistinction, each patient in our study diagnosed as having MVP demonstrated a *mobile* mid-systolic click. Furthermore, the presence of hypertrophic cardiomyopathy, atrial myxoma, ventricular septal defect or aneurysm, and pneumothorax was excluded by echocardiography and chest X-ray. Thus, within the conditions of our study, the mobile nonejection systolic click was a reasonable diagnostic standard for MVP. That nonejection systolic clicks may occasionally occur in the absence of M-mode echocardiographic evidence of MVP can be attributed to the limitations of this technique in viewing mitral valve motion. In his letter, Dr. Bianchi suggests that left ventricular angiography may be a more suitable diagnostic standard for MVP. However, most studies seeking to establish angiographic criteria for MVP have employed the nonejection systolic click with or without late systolic murmur (confirmed by auscultation or phonocardiography) as a diagnostic standard.[5] Also, recent studies have demonstrated marked intra- and interobserver variability in the angiographic diagnosis of MVP[6] thus casting doubt on the usefulness of this technique as a diagnostic standard. Two-dimensional echocardiography may prove to be the most useful method of all for detecting MVP. But to date there have been no large studies comparing the 2-Dimensional echocardiograms of patients with MVP with those of normal subjects. Thus, it seems premature to identify 2-dimensional echocardiography as the diagnostic standard for MVP.

6. **Kennett JD, Rust PF, Martin RH, Parker BM, Watson LE.** Observer variation in the angiographic diagnosis of mitral valve prolapse. Chest 1981;79:146–150.

The report by Haikal et al[1] quoted a 4% prevalence of mitral valve prolapse (MVP) in the general population. In our opinion, that is an underestimation and the range should be between 5 and 10%,[2,3] as indeed reflected by the authors' own findings of 11 MVP subjects among 100 asymptomatic volunteers.

We agree with the authors that because of the high prevalence of MVP and its clinical implications, the diagnostic criteria used should possess "reasonable sensitivity and a high degree of specificity." We disagree with the reported specificity of the last 3 echocardiographic criteria tested in Table I, except thickening of the mitral leaflets. According to the authors' data, the specificity of multiple parallel systolic echoes, the increased early diastolic excursion of anterior mitral leaflet, and the abutment of the anterior mitral leaflet against the ventricular septum should be 22, 58, and 77%, respectively, instead of the reported 78, 42, and 23%.[1]

INTRANODAL CONDUCTION PATHWAYS IN COMPLETE TRANSPOSITION OF THE GREAT ARTERIES

In the Symposium on Postoperative Congenital Heart Disease in Adults in the September 1982 issue of the Journal, I was particularly interested in the reports on conduction tissues by Barati and Lev[1] and Vetter and Horowitz.[2] There appears to be a highly significant difference in their conclusions on the results of surgery for complete transposition. On page 595, Vetter and Horowitz, quoting the important study of Wittig et al,[3] state that damage to the preferential intranodal conduction pathways "was sufficient to compromise activation of the A-V node and produce junctional rhythm." However, on page 586, Bharati and Lev state, "With time, this pathway may become fibrotic, yielding A-V block." The latter finding, if true, is of considerable significance, yet Bharati and Lev do not give the source of their data. Is this a speculative comment, or have they firm evidence to confirm this prognostication?

REPLY: In response to the question of whether disruption of the pathways between the sinoatrial and atrioventricular (AV) nodes will result in some form of AV dissociation, we refer to an earlier report of ours[1]: In case 1 there was sinus rhythm alternating with junctional rhythm in the last year of the child's life. There was also first-degree AV block. Pathologically, we found that only part of the superior preferential pathway remained, and it was interrupted in part by sutures. In case 2, 2 months before death, there was first-degree AV block which progressed to second-degree with 2:1 conduction alternating with a junctional rhythm with AV dissociation. Pathologically, the superior and middle preferential pathways were replaced by fibrous tissue and by the pericardial prosthesis. The inferior preferential pathway had been removed surgically.

Thus, our work demonstrates that operation on the conduction pathways may be important in preventing arrhythmias and various degrees of AV block. Both cases also revealed that the approaches to the sinoatrial and the AV node were markedly fibrosed. In case 1 the sinoatrial node was interrupted by sutures and in case 2 it was considerably fibrosed. Therefore, we concluded the following: "... Our work does not determine the importance of preserving the internodal pathways, which were also found to be disrupted in our cases. In this regard, the work of Holsinger and associates[2] is pertinent. These workers found in their experiments on dogs that the integrity of at least the superior atrial preferential pathway was important in atrial conduction. When the posterior internodal pathway was divided, there was no change in the PR time. Dividing the middle pathway still did not cause a delay in atrial conduction. However, division of the remaining anterior pathway did produce a delay in atrial conduction. When the 3 pathways were interrupted, nodal rhythm occurred in 7 of 10 dogs. Similar findings were obtained by Waldo,[3] Pereira Leite,[4] and their co-workers. Thus experimental evidence suggests that in addition to retaining the integrity of the approaches to the SA and AV nodes, it is advisable to retain the superior internodal pathway in the Mustard procedure." TERM OBLITERATION OBSESSION (TOO)

The manifestation of a new disease always excites interest, and we draw your attention to a hitherto undescribed syndrome: term obliteration obsession (TOO). TOO is characterized by an overwhelming compulsion to deliberately abbreviate real nouns (DARN), and indeed any other word which comes within the sphere of this strange and acquired Machiavellian malady. The following examples were culled at random from current reports: ALAD for abnormal left axis deviation; AWP for alternating Wenckebach phenomenon; CPB for cardiopulmonary bypass; CSRT for corrected sinoatrial recovery time; SNCL for sinus node cycle length; RHR for resting heart rate; IHR for intrinsic heart rate; and IHRo for observed intrinsic heart rate. TOO presupposes immediate decipherment (PID) so that understanding (STU) is possible. TOO is thus specifically designed to frustrate orderly reading (FOR), thereby causing a predictable response: worry over redundant diminutive stupidity (WORDS). An unexpected and remarkable feature of TOO is that it rarely, if ever, affects single words, 2 being the minimum requirement for TOO. This exception would therefore seem to be the obvious starting point for further research. TOO is random, disorderly, illogical, unpredictable, and to no purpose. The nondifferentiating character of the disease is evident from the fact that the same acronym may be used for different conditions: for example, MI for myocardial infarction as well as mitral insufficiency. TOO should therefore be regarded as a primitive undifferentiated lingering malignant disease. TOO is endemic in the United States and is especially rampant among cardiologists, having indeed reached epidemic proportions. Electrophysiologists, in particular, are very prone to this affliction. Mortality is uncommon but morbidity profound. There is no known treatment.

The features of this syndrome may thus be presented succinctly as follows: Term obliteration obsession deliberately abbreviates real nouns so that understanding presupposes immediate decipherment, frustrating orderly reading by worrying over redundant diminutive stupidity. Or, to TOO it so that it is even more succinct: TOO DARN STU PID FOR WORDS.

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

CARDIAC PACING ELECTROPHYSIOLOGY and PACEMAKER TECHNOLOGY

Edited by G.A. FERUGLIO, M.D., F.A.C.C.

Proceedings of the 2nd European Symposium on Cardiac Pacing

375 Contributions, 1,000 Authors, c. 1,200 pages (illus), $ 112 (Proceedings and Mini-Courses), $ 26 (mini-courses apart).

In only two decades, since the first pacemaker was implanted in man, the art and science of electrical pacing of the heart has shown a tremendous growth. However, the very important changes and the rapid growth of the last few years have made a reappraisal of conventional concepts on the selection of patients and pacing systems essential.

A comprehensive and unique study of all these recent developments was made at the Second European Symposium on Cardiac Pacing, the proceedings of which are presented in this book.

With the aim of expanding the educational content of the Symposium, two Mini-courses were also included on two topics of current interest: **"Pacing as a Diagnostic Tool"** and **"Physiological Pacing".**

These proceedings reflect the basic structure of the Symposium and offer the reader a thorough documentation on the wealth of information originanting from the 52 sessions of the scientific programme. The insights and information presented in the **375 contributions**, by nearly 1,000 authors offer a broad view of the ongoing research and clinical progress in the field.

Another reason we're called PACESETTER.

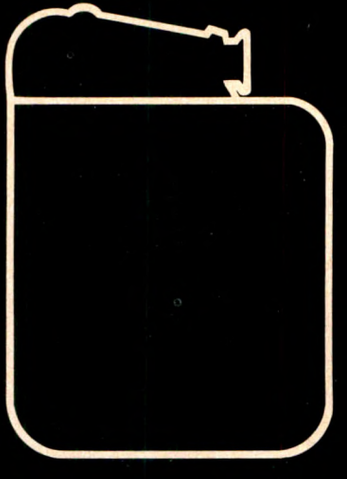
A Pacesetter commitment

The Pacesetter Programalith® A-V. Smaller, with more sophisticated telemetry, and the first dual-chamber pacemaker that not only tells you what it *should* be doing, but also what it is *actually* doing.

Multi-programmability, non-invasive monitoring and programming of *six* parameters—Pacesetter innovations—are standard to the Model 223 A-V. In addition, when coupled with our Model 398E Programming/Telemetry System, *measured* values of rate, pulse current, pulse voltage, pulse energy, pulse charge, battery voltage and A-V delay can be retrieved as well. And, a refined circuitry design results in less battery drain—meaning longer life for the pacemaker's energy system.

Lead impedance, battery impedance and battery current are shown both on the programmer's digital display and on the printout for your patient's permanent record.

DVI pacing has been shown to be desirable for those patients who require more than single-chamber pacing (VVI or AAI), yet do not require DDD pacing. In the innovative Programalith A-V sequential pacemaker, Pacesetter Systems, Inc. has created the most advanced such device available today.



Actual size.

Dual-chamber pacing.

Voltage	2.8 V	
Dimensions:	6.3 x 4.7 x 1.17 cm	
Weight	68 gms	
Volume	30 cc	
Density	2.3 gm/cc (Approximately)	
Hermetic Case	Titanium	
Connector Material	Epoxy	
Projected (theoretical) Life	9.6 years (VVI Mode)	
Recommended Replacement Time:		
Magnet Rate Decrease	from 90 to 77 ppm	
Pulse Width Increase	25%	
Pacing Configuration:	223-dual unipolar	

INDICATIONS The Pacesetter Model 223 Programalith® is a dual-chamber A-V sequential pacemaker specifically indicated for therapeutic control of conduction disorders requiring restoration of both rate and A-V synchrony. In the A-V sequential mode (DVI), the Model 223 has application for patients with extensive myocardial infarction with A-V block and sinus bradycardia. The Model 223 may also be programmed for single-chamber pacing in either ventricle or atrium.

CONTRAINDICATIONS Medical literature indicates no known contraindications to the use of pacemakers as a therapeutic means for heart-rate control. However, sequential atrial-ventricular pacing modes are contraindicated in the presence of atrial flutter and fibrillation.

WARNINGS Although special shielding and filters protect Pacesetter Pulse Generators against defibrillation pulses of up to 400 Watt seconds, defibrillator paddles should not be placed near the pulse generator and pacer function should be verified following defibrillatory charges. Caution should be exercised also with diathermy and electrosurgical units which produce high field strength signals, possibly resulting in suppression of the device's output, reversion to asynchronous mode and/or overheating of the metallic components. Pulse generators must not be sterilized by steam autoclaving or gamma radiation nor cleaned ultrasonically.

PRECAUTIONS Physicians should be aware that any pulse generator will ultimately cease to function from battery depletion and may fail at any time owing to random malfunction. Pacesetter Pulse Generators have been designed so that the average life of the circuitry will greatly exceed the expected life of the power source. As all critical circuitry and the battery are hermetically sealed, the package is virtually unaffected by the body environment; therefore, the longevity is determined almost entirely by the battery. Insufficient time has passed to completely determine various factors that may affect the life expectancy of the present battery configurations. Thus any estimates of pulse generator longevity must be based on theoretical projections of available date, principally accelerated test data, as well as expected pacing characteristics. Recommended replacement times, indications for end-of-life and longevity factors are discussed thoroughly in Pacesetter's appropriate physicians' manual for the unit to be implanted and should be consulted prior to implantation.

POTENTIAL COMPLICATIONS & SIDE EFFECTS Lead displacement/fracture, cardiac tamponade, muscle or nerve stimulation, embolism, infection, erosion of lead or pulse generator through skin and body rejection phenomena are possible.

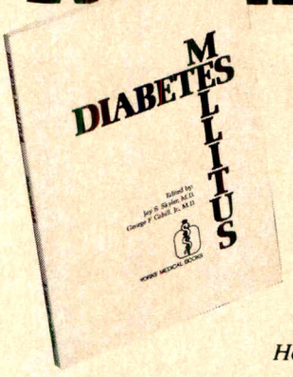
DIABETES MELLITUS



From the publishers of the American Journal of Medicine

Jay S. Skyler, M.D.,
University of Miami School of Medicine

George F. Cahill, Jr., M.D.,
Harvard Medical School and Howard Hughes Medical Institute

60 internationally prominent contributors provide in 26 papers a comprehensive overview of the current thinking on the causes, mechanisms, treatment and complications of diabetes. Featured topics include:

- The causes of diabetic inheritance
- Mechanisms of diabetes
- New developments in the treatment of diabetes
- Human insulin produced by recombinant DNA technology

If it is important to you in your practice to stay up-to-date on the latest developments in Diabetes Mellitus and you need a quick reference on the topic, then this is the book for you.

(clothbound) $29.50 (paperbound) $19.50

THE BRITISH COUNCIL
INTERNATIONAL MEDICAL COURSE

PAEDIATRIC CARDIOLOGY
10–22 July 1983 in Cambridge

This course on the management of congenital heart disease will cover pre- and post-operative care, atrioventricular septal defects, univentricular hearts, truncus arteriosus, total anomalous pulmonary venous drainage, atrial isomerism, interrupted aortic arch, pulmonary atresia with and without ventricular septal defect, tetralogy of Fallot, complete and corrected transposition, double outlet right ventricle and arrhythmias. For each topic the pathological anatomy, clinical presentation, results of invasive and non-invasive investigation and medical and surgical management will be covered. There will be one half-day devoted to computer applications in paediatric cardiology with the emphasis on simplicity and a further half-day on fetal echocardiography.

The course will be held at Christ's College, Cambridge under the direction of PROFESSOR FERGUS MACARTNEY, Vandervell Professor of Paediatric Cardiology, Institute of Child Health, University of London. It is intended for doctors with several years' experience in the field of paediatric cardiology or paediatric cardiac surgery. There are 35 vacancies.

Fee £690 (Residential), £405 (Non-residential).

Further Information and Application Forms Can Be Obtained From Your Local Overseas Representative of The British Council or From **Courses Department, The British Council, 65 Davies Street, London W1Y 2AA, England.**

CARDIOLOGISTS

Private Practice Opportunities Tailor-Made For You.

Deciding upon the community where your skills are in the greatest demand can be an arduous task. Your choice is important to your career, and Humana, with more than 90 hospitals nationwide, can help you to select the location that best suits your professional and personal needs.

Furthermore, Humana can assist you in establishing a private practice. Whether you desire a solo, group or associate arrangement, Humana can make it happen. And, in many cases, financial assistance is available.

Humana offers you a wealth of choices from which to choose and currently we have outstanding Cardiology opportunities in the following states:

- **Alabama**
- **Florida**
- **Georgia**
- **Virginia**
- **Texas**
- **Kentucky**

So get moving. For further information, send your curriculum vitae to Gordon Crawford, Manager, Professional Relations or call TOLL-FREE: 800-626-1590. There is no obligation. Humana, The Hospital Company, Dept. M-4, 1800 First National Tower, Louisville, Kentucky 40201.

REINFORCES
THE STRENGTH,
REDUCES THE WEAKNESS
OF BETA-BLOCKERS
© 1982 Warner-Lambert Company

FOR ANGINA PROPHYLAXIS*

SUSTAINED RELEASE

2.5, 6.5, 9.0 mg CAPSULES

NITROSTAT® SR

(nitroglycerin capsules)

■ complementary therapeutic effect: nitrates and beta-adrenergic blocking agents reduce myocardial oxygen demand by different mechanisms

Mechanism I: Nitrates reduce myocardial oxygen requirement by acting on systemic circulation. Their vasodilator action decreases venous return and systemic arterial resistance, thus improving the balance between the need and supply of oxygen. Reduction in the myocardial oxygen requirement appears to be the major action of nitrates in relieving typical angina. However, selective dilatation of large coronary vessels by nitrates may be the primary mechanism by which they benefit patients with angina due to coronary spasm.[1]

Mechanism II: In contrast, beta-blockers block the beta receptor sites in the heart itself. They work by reducing the heart rate and the force of contraction, thereby lowering oxygen demand. In addition to cardiac output and heart rate, blood pressure is also decreased.

Beta-blockers may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction.

■ diminished side effects: some of the negative aspects of the effects of each drug are reduced. For example, concomitant nitrates oppose the increased ventricular size, filling pressure, and end-diastolic pressure caused by beta-adrenergic antagonists.[1]

The effects of NITROSTAT® SR and a beta-blocker are complementary. The result can be improved therapy for angina prophylaxis.

■ all day and all night prophylactic action with just two or three daily doses*

How Supplied: 2.5-mg and 6.5-mg strengths, in bottles of 60 and 100 capsules. Also, 9.0-mg strength, in bottles of 60 capsules.

Please see next page for brief summary of prescribing information.

NITROSTAT® SR...Backed by the experience and reputation of PARKE-DAVIS

*Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows. "Possibly" effective: For the management, prophylaxis or treatment of anginal attacks. Final classification of the less-than-effective indication requires further investigation.

REFERENCE: 1. Needleman P, Johnson EM Jr: Vasodilators and the treatment of angina, in Gilman AG, Goodman LS and Gilman A (eds): Goodman and Gilman's The Pharmacological Basis of Therapeutics, ed 6. New York, Macmillan Publishing Co, Inc, 1980, pp 819-833.

NITROSTAT® SR CAPSULES
(nitroglycerin capsules)
SUSTAINED RELEASE

Before prescribing, please see full prescribing information. A Brief Summary follows:

INDICATION: Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indication as follows.

"Possibly" effective: For the management, prophylaxis or treatment of anginal attacks.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATIONS:
Acute or recent myocardial infarction, severe anemia, closed-angle glaucoma, postural hypotension, increased intracranial pressure and idiosyncrasy to the drug.

WARNINGS:
Capsules must be swallowed. FOR ORAL, NOT SUBLINGUAL USE. Nitrostat SR Capsules are not intended for immediate relief of anginal attacks.

PRECAUTIONS:
Intraocular pressure may be increased; therefore, caution is required in administering to patients with glaucoma. Tolerance to this drug and cross-tolerance to other organic nitrites and nitrates may occur. If blurring of vision, dryness of mouth or lack of benefit occurs, the drug should be discontinued.

ADVERSE REACTIONS:
Severe and persistent headaches, cutaneous flushing, dizziness and weakness. Occasionally, drug rash or exfoliative dermatitis, and nausea and vomiting may occur; these responses may disappear with a decrease in dosage. Adverse effects are enhanced by ingestion of alcohol, which appears to increase absorption from the gastrointestinal tract.

DOSAGE AND ADMINISTRATION:
Administer the smallest effective dose 2 or 3 times daily, at 8- to 12-hour intervals, unless clinical response suggests a different regimen. Discontinue if not effective. 0883G010

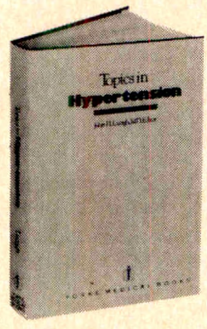
Laragh's eagerly awaited new book on the silent killer

TOPICS IN HYPERTENSION



Edited by
John H. Laragh, MD
Master Professor of Medicine
Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center

644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

INSTRUCTIONS TO AUTHORS

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal*. All accepted manuscripts are subject to editing to aid understanding and conserve space.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

TITLE PAGE, SUMMARY, AND ABSTRACT: Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

REFERENCES: In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

Journal: Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.

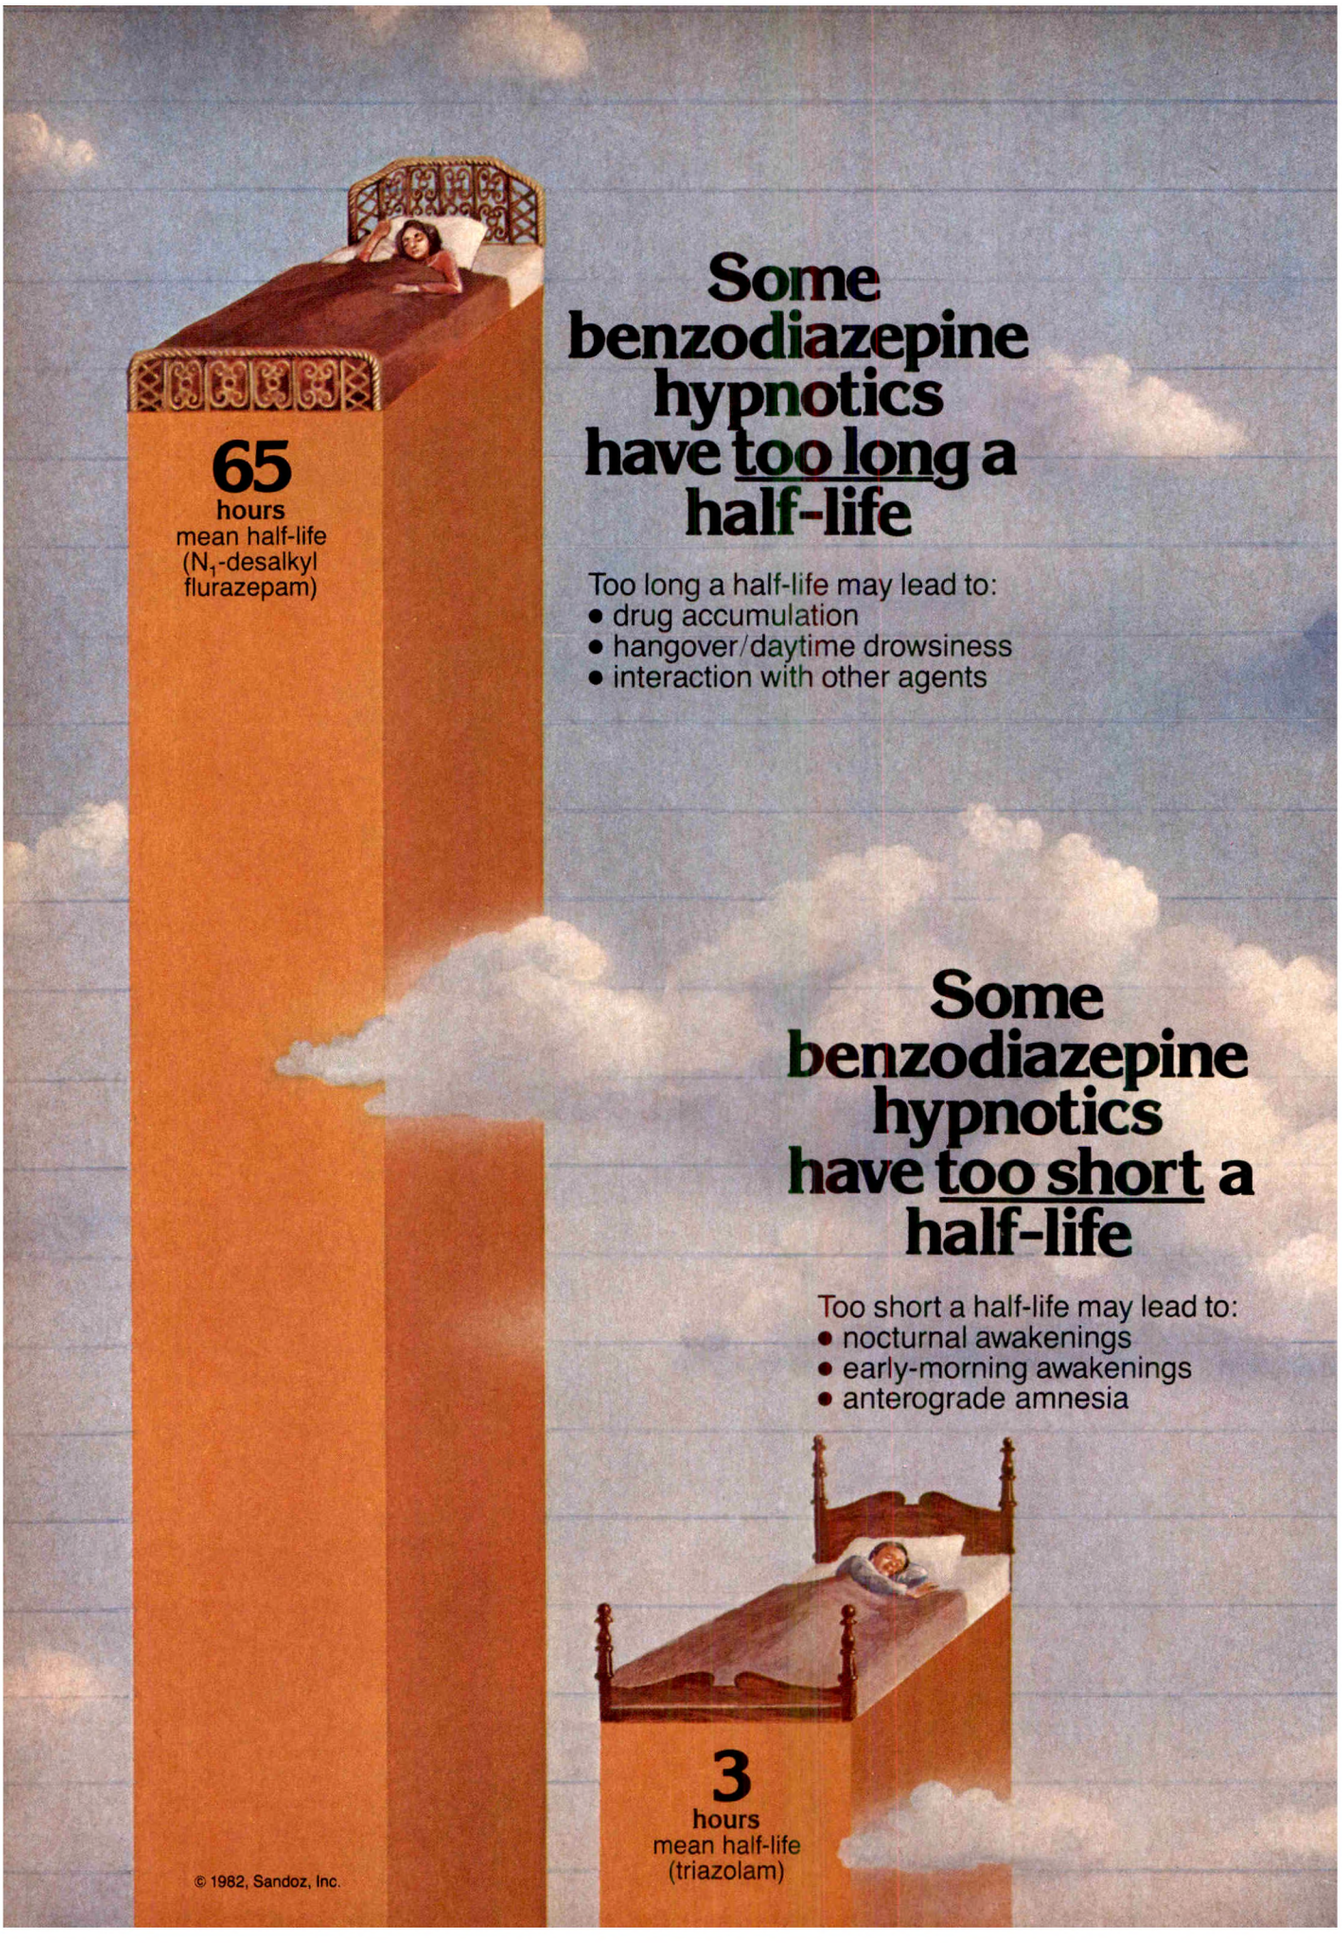
Chapter in Book: Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.

Book: Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

FIGURES: Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

TABLES: Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

REPRINTS: Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.



65
hours
mean half-life
(N_1-desalkyl
flurazepam)
Some benzodiazepine hypnotics have too long a half-life
Too long a half-life may lead to:
• drug accumulation
• hangover/daytime drowsiness
• interaction with other agents
Some benzodiazepine hypnotics have too short a half-life
Too short a half-life may lead to:
• nocturnal awakenings
• early-morning awakenings
• anterograde amnesia

Restful sleep, alert awakening

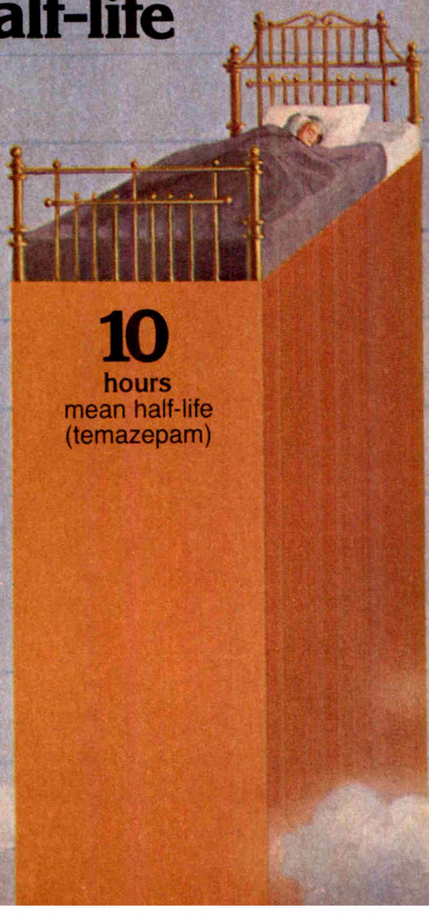
RESTORIL®

C IV

15 mg
30 mg
capsules

(temazepam)

RESTORIL®
(temazepam)
has an appropriate half-life



A half-life (mean of 10 hours) that parallels normal sleep time:

- patient gets 7-8 hours sleep
- most medication gone by morning
- patient awakes alert and refreshed
- minimal side effects
- insignificant accumulation

Please see brief summary of prescribing information on next page.

Restful sleep, alert awakening

RESTORIL® (temazepam) 15 mg 30 mg capsules

A more appropriate half-life

One 30-mg capsule, h.s.—*usual adult dosage.*
One 15-mg capsule, h.s.—*recommended initial dosage for elderly and/or debilitated patients.*

INDICATIONS AND USAGE: Restoril® (temazepam) is indicated for the relief of insomnia associated with complaints of difficulty in falling asleep, frequent nocturnal awakenings, and/or early morning awakenings. Since insomnia is often transient and intermittent, the prolonged administration of Restoril is generally not necessary or recommended. Restoril has been employed for sleep maintenance for up to 35 consecutive nights of drug administration in sleep laboratory studies.

The possibility that the insomnia may be related to a condition for which there is more specific treatment should be considered.

CONTRAINDICATIONS: Benzodiazepines may cause fetal damage when administered during pregnancy. An increased risk of congenital malformations associated with the use of diazepam and chlordiazepoxide during the first trimester of pregnancy has been suggested in several studies. Also, ingestion of therapeutic doses of benzodiazepine hypnotics during the last weeks of pregnancy has resulted in neonatal CNS depression. Restoril is contraindicated in pregnant women. Consider a possibility of pregnancy when instituting therapy or whether patient intends to become pregnant.

WARNINGS: Patients receiving Restoril (temazepam) should be cautioned about possible combined effects with alcohol and other CNS depressants.

PRECAUTIONS: In elderly and/or debilitated patients, it is recommended that initial dosage be limited to 15 mg. The usual precautions are indicated for severely depressed patients or those in whom there is any evidence of latent depression; it should be recognized that suicidal tendencies may be present and protective measures may be necessary.

If Restoril is to be combined with other drugs having known hypnotic properties or CNS-depressant effects, due consideration should be given to potential additive effects.

Information for Patients: Patients receiving Restoril should be cautioned about possible combined effects with alcohol and other CNS depressants. Patients should be cautioned not to operate machinery or drive a motor vehicle. They should be advised of the possibility of disturbed nocturnal sleep for the first or second night after discontinuing the drug.

Laboratory Tests: The usual precautions should be observed in patients with impaired renal or hepatic function. Abnormal liver function tests as well as blood dyscrasias have been reported with benzodiazepines.

Pregnancy: Pregnancy Category X. See Contraindications.

Pediatric Use: Safety and effectiveness in children below the age of 18 years have not been established.

ADVERSE REACTIONS: The most common adverse reactions were drowsiness, dizziness and lethargy. Other side effects include confusion, euphoria and relaxed feeling. Less commonly reported were weakness, anorexia and diarrhea. Rarely reported were tremor, ataxia, lack of concentration, loss of equilibrium, falling and palpitations. And rarely reported were hallucinations, horizontal nystagmus and paradoxical reactions, including excitement, stimulation and hyperactivity.

Restoril is a controlled substance in Schedule IV. Caution must be exercised in addiction-prone individuals or those who might increase dosage.

DOSAGE AND ADMINISTRATION: *Adults:* 30 mg usual dosage before retiring; 15 mg may suffice in some. *Elderly and/or debilitated:* 15 mg recommended initially until individual response is determined.

SUPPLIED: Restoril (temazepam) capsules—15 mg maroon and pink, imprinted "RESTORIL 15 mg"; 30 mg, maroon and blue, imprinted "RESTORIL 30 mg". Packages of 100, 500 and ControlPak® packages of 25 capsules (continuous reverse-numbered roll of sealed blisters). (RES-Z2 11/1/81)

Before prescribing, see package insert for full product information.

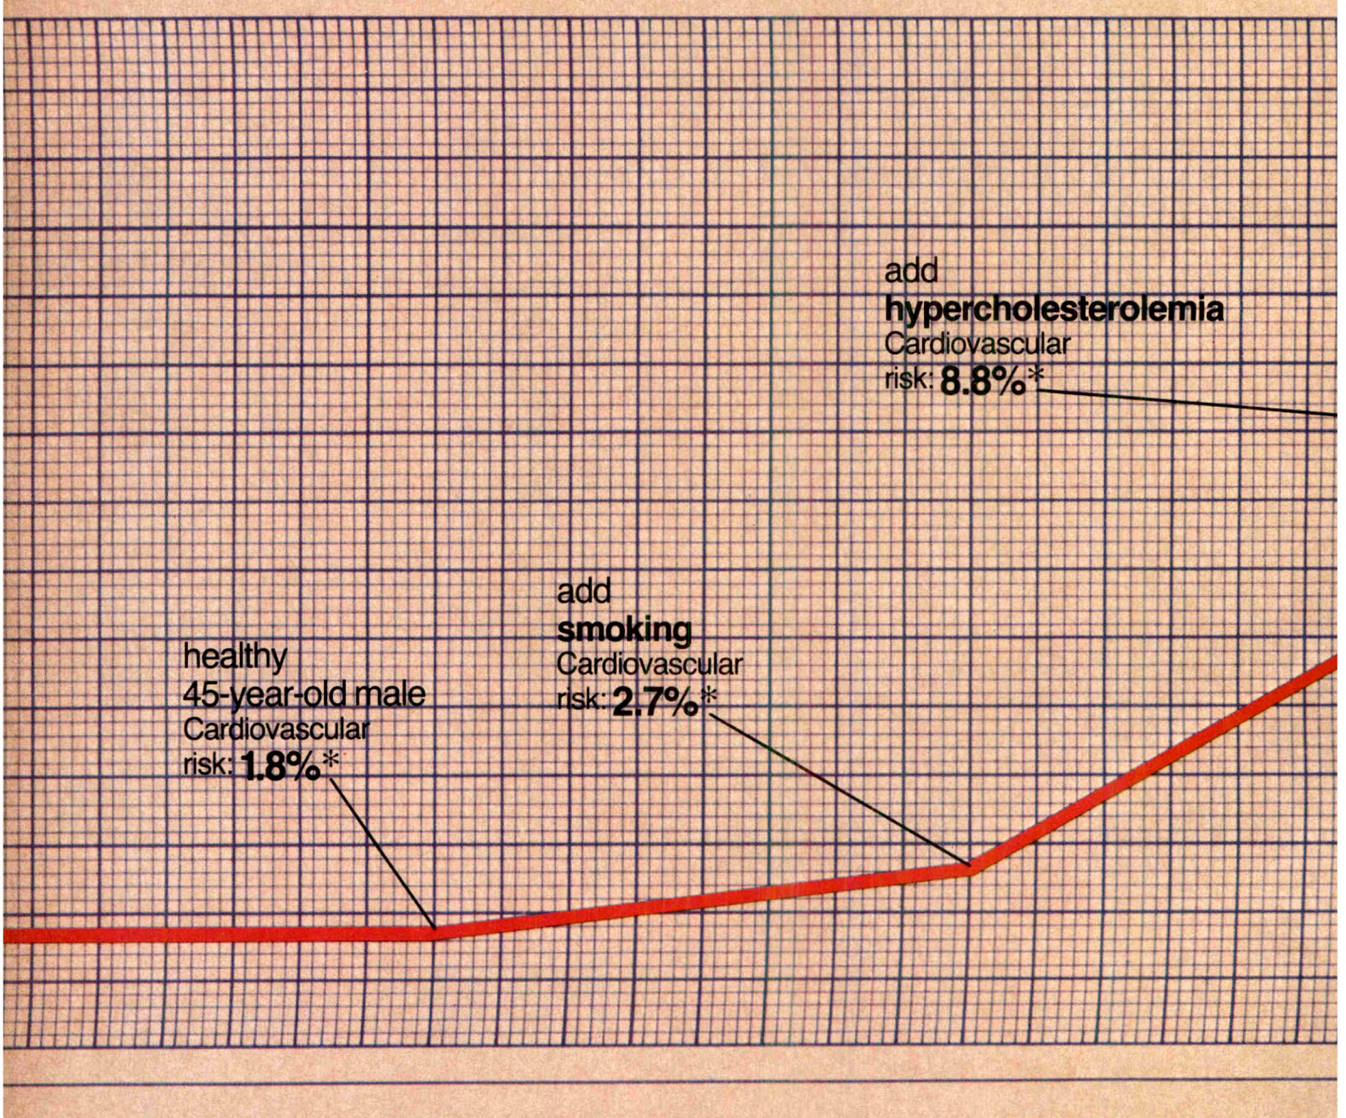
In hypertensive patients:

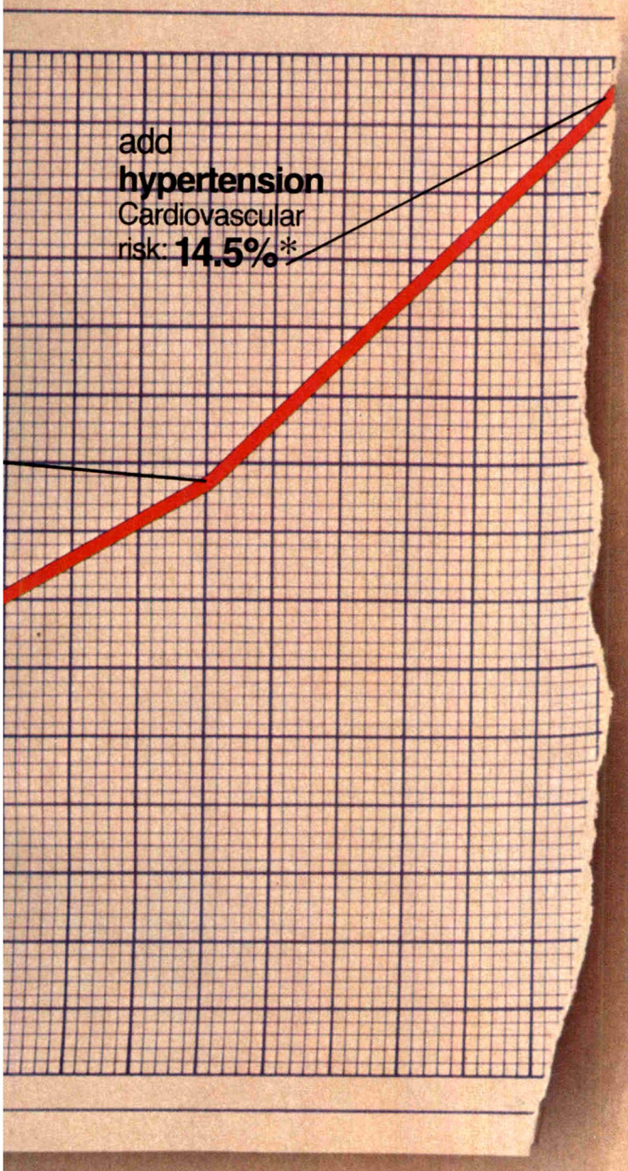


Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

Consider the Risks



- When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

- Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]
- Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

Please see Minipress brief summary on following page.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

Minipress® (prazosin HCl) Capsules 1mg, 2mg, 5mg

B.I.D. Dosage Convenience

BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*
INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings.)

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

More detailed information available on request.

CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

William C. Roberts, M.D.
Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.

Dean T. Mason, M.D.
Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California

Mary Allen Engle, M.D.
Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York

Lawrence H. Cohn, M.D.
Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066

What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended." Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

"...recommend...to any reader interested in the literature of cardiology." Irwin R. Callen, M.D. JAMA, November, 1981

SPECIAL DISCOUNT OFFER

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

Yorke Medical Books, Box C-757, Brooklyn, NY 11205 AJCD3

☐ Please send me a copy of the 1982 edition at the full price of $45.00. I do not wish to place a standing order.

☐ Enclosed is my check for _____ Yorke pays postage and handling. (Same return privilege)
(New York residents add appropriate sales tax. Add $5.00 per book for orders outside the U.S. and Canada.)

☐ Please bill my ☐ VISA ☐ MasterCard (same return privilege)
Exp. date _____ Card No. _____ M/C Interbank No. _____

☐ Please bill me plus postage and handling (U.S. and Canadian orders only)

Your patients deserve the best ECG analysis they can get.

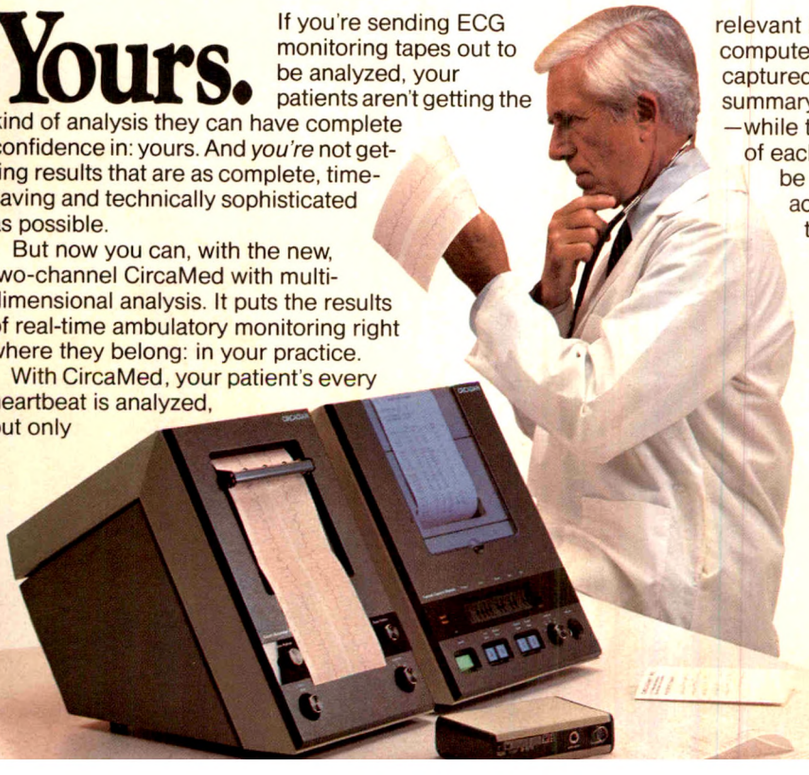
Yours. If you're sending ECG monitoring tapes out to be analyzed, your patients aren't getting the kind of analysis they can have complete confidence in: yours. And *you're* not getting results that are as complete, time-saving and technically sophisticated as possible.

But now you can, with the new, two-channel CircaMed with multi-dimensional analysis. It puts the results of real-time ambulatory monitoring right where they belong: in your practice.

With CircaMed, your patient's every heartbeat is analyzed, but only relevant information is recorded, under micro-computer control. Up to two days of patient data are captured on two multi-dimensional channels; a summary is then printed in your office within minutes —while the patient is still there. A strip chart record of each 10-second ECG measurement can also be quickly produced for further diagnostic accuracy. And because CircaMed is simple to use, a specially trained technician isn't required.

That means now neither you nor your patients have to worry about who's in charge of their ECG analysis: you are. You can both count on getting results quickly, economically and with complete confidence.

To find out how easy it is to bring ECG analysis into your practice, write us today for a brochure or demonstration: 777 Palomar Avenue, Sunnyvale, CA 94086. Or call: (800) 538-1772. In California (408) 738-8550.



CIRCADIAN

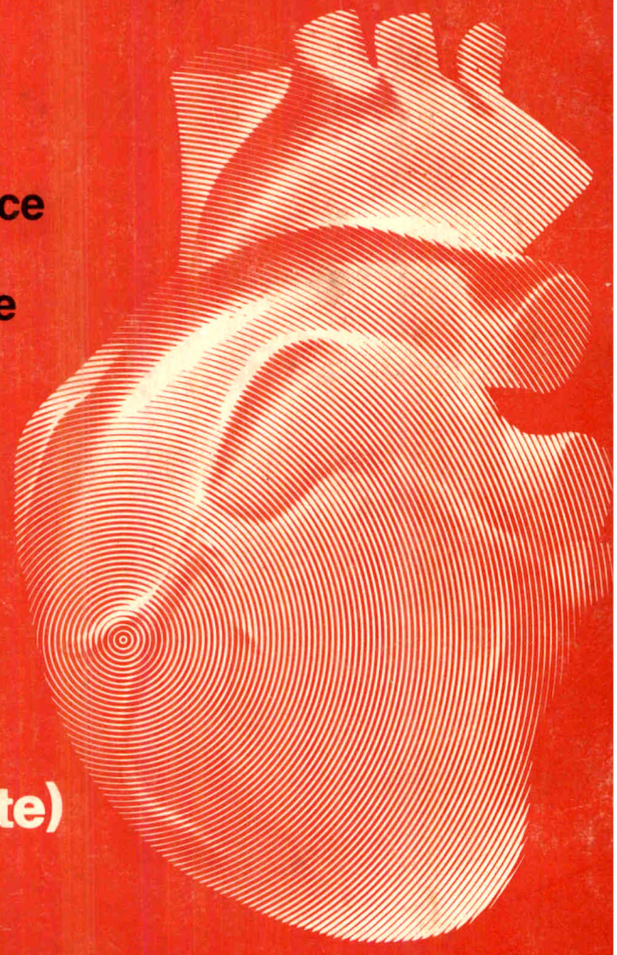
Leaders in real-time ECG analysis.

The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.



CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decrease excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digox (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases whe the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: Th drug should be used with caution due to excretion of the quinidine in breast milk. ADVERS REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/ disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTES TINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QR complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricul tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMA TOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulo cytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, an syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasi blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, nigh blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intens pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episod vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribin Information.

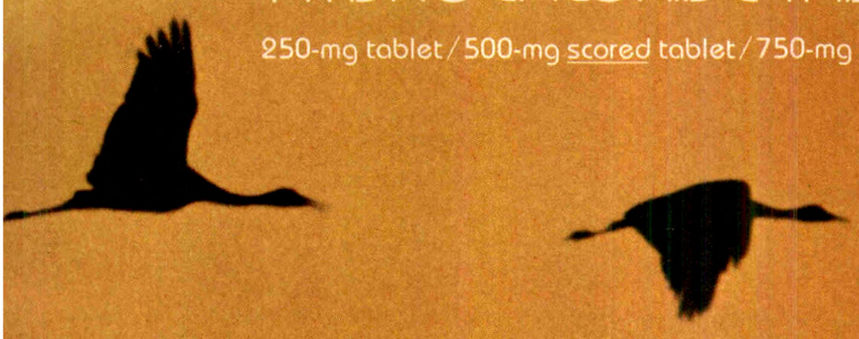
Return to a natural cardiac rhythm

SUSTAINED RELEASE

Procan® SR

(PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet / 500-mg scored tablet / 750-mg scored tablet



Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

Administered half as often as conventional oral procainamide

Wide versatility in cardiac conditions

Can be used concomitantly with digoxin

Ideal maintenance therapy

If in the past you have substituted another medication for maintenance therapy because of compliance problems with conventional oral procainamide, now you can logically turn to the modern oral procainamide.

Procan SR... the original sustained-release oral procainamide

PARKE-DAVIS
Division of Warner-Lambert Company
Morris Plains, New Jersey 07950

Please see next page for brief summary of prescribing information.

Procan® SR
(procainamide hydrochloride tablets)
SUSTAINED RELEASE

Before prescribing, please see full prescribing information.
A Brief Summary follows.

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS AND USAGE: Oral procainamide is indicated in the treatment of premature ventricular contractions and ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: It has been suggested that procainamide be contraindicated in patients with myasthenia gravis. Hypersensitivity to the drug is an absolute contraindication; in this connection, cross-sensitivity to procaine and related drugs must be borne in mind. Procainamide should not be administered to patients with complete atrioventricular heart block. Procainamide is also contraindicated in cases of second-degree and third-degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS: General —During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Instances of a syndrome resembling lupus erythematosus have been reported in connection with maintenance procainamide therapy. The mechanism of this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain are common symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural effusion, and pericarditis may occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia have been reported which may be related to this syndrome.

Laboratory Tests—Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals. The drug should be discontinued if there is a rising titer (antinuclear antibody) or clinical symptoms of LE appear. The LE syndrome may be reversible upon discontinuation of the drug. If discontinuation of the drug does not cause remission of the symptoms, steroid therapy may be effective. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, steroid suppressive therapy may be used concomitantly with procainamide. It is recommended that tests for lupus erythematosus be carried out at regular intervals in patients receiving maintenance procainamide therapy.

Routine blood counts are advisable during maintenance procainamide therapy.

ADVERSE REACTIONS: Agranulocytosis has occasionally followed the repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tract infection. If any of these should occur, and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

A syndrome resembling lupus erythematosus has been reported (see PRECAUTIONS).

Hypotension following oral administration is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

Reactions consisting of fever and chills have also been reported, including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Bitter taste, diarrhea, weakness, mental depression, giddiness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

DOSAGE AND ADMINISTRATION: Procan SR (procainamide hydrochloride) tablets are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every six hours instead of the more frequent every-three-hour dosing interval required for standard preparations of oral procainamide hydrochloride. The convenient six-hour dosing schedule may encourage patient compliance.

Ventricular tachycardia—Treatment with standard procainamide hydrochloride is recommended until the tachycardia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1 g of standard procainamide hydrochloride followed thereafter by a total daily dose of 50 mg/kg of body weight given at three hour intervals. The suggested oral dosage for premature ventricular contractions is 50 mg/kg of body weight daily given in divided doses at three-hour intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg of body weight daily given in divided doses at six-hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0.5 g every six hours; patients weighing between 55 and 91 kg (120 and 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (200 lb), 1 g every six hours.

Atrial fibrillation and paroxysmal atrial tachycardia—Treatment with standard procainamide hydrochloride is recommended until the arrhythmia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows. An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Standard procainamide hydrochloride may then be given at a dose of 0.5 to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every six hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

HOW SUPPLIED: Procan SR 250 mg (green, film-coated tablet, P-D 202) is available in bottles of 100 (N 0071-0202-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0202-40). Each sustained-release tablet contains 250 mg procainamide hydrochloride.

Procan SR 500 mg (yellow, scored, film-coated tablet, P-D 204) is available in bottles of 100 (N 0071-0204-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0204-40). Each sustained-release tablet contains 500 mg procainamide hydrochloride.

Procan SR 750 mg (orange, scored, film-coated tablet, P-D 205) is available in bottles of 100 (N 0071-0205-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0205-40). Each sustained-release tablet contains 750 mg procainamide hydrochloride.

Storage—Protect from moisture. Store bottles below 86° F (30° C). Store unit-dose packages at controlled room temperature, 59°-86° F (15°-30° C).

The end of the "one-defibrillator-meets-all-needs" theory.

From the field to the various departments in the hospital, cardiac care offers more problems and situations than one system can efficiently handle.

Which is why Physio-Control has a family of LIFEPAK® defibrillator/monitors. Each one gives you specialized features designed to meet your specific needs.

You can depend on the whole LIFEPAK family for ease of operation and outstanding reliability. And service from the best in the industry. Physio-Control.

You can't beat the system.
LIFEPAK defibrillator/monitors from Physio-Control.

In Cardiac Edema*...

ach capsule contains 50 mg. of
yrenium® (brand of triamterene)
nd 25 mg. of hydrochlorothiazide.

yazide® is a trademark of SK&F Co.

When You Need to Conserve K^+

SK&F CO.
SmithKline company
Carolina, P.R. 00630

Serum K^+ and BUN should be checked periodically (see Warnings).

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

★ **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, Dyazide should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on Dyazide when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with Dyazide. The following may occur: transient elevated BUN or creatinine or both; hyperglycemia and glycosuria (diabetic insulin requirements may be altered); hyperuricemia and gout; digitalis intoxication (in hypokalemia); decreasing alkali reserve with possible metabolic acidosis. Dyazide interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with Dyazide, but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and Dyazide should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Dyazide should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth, anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions, nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances, postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on Dyazide, although a causal relationship has not been established.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

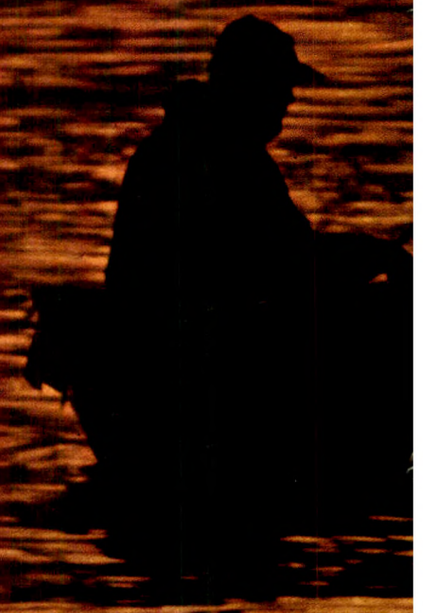
The Secure Diabetic



When diet alone has failed in NIDDM, successful management with diet and Diabinese® (chlorpropamide) is a source of great security to both patient and physician.

By safely lowering blood sugar, once-a-day Diabinese provides uncomplicated control every day for nearly a million secure diabetics.*

Diabinese is the most widely prescribed oral anti-diabetic agent. Its extensive record of efficacy and safety gives physicians confidence that their patients will be well controlled...while the once-daily regimen, regardless of dosage, helps assure compliance. And, Diabinese is economical.

*As with all sulfonylureas, hypoglycemia may occur with Diabinese, especially when dosage is not properly adjusted to the patient's requirements.

Diet & Diabinese (chlorpropamide)

Tablets 100 mg and 250 mg

A proven regimen... continue it with confidence.

BRIEF SUMMARY
DIABINESE* (chlorpropamide) Tablets

Contraindications: Diabinese is not indicated in patients having juvenile or growth-onset diabetes mellitus, severe or unstable "brittle" diabetes, and diabetes complicated by ketosis and acidosis, diabetic coma, major surgery, severe infection, or severe trauma.
Diabinese is contraindicated during pregnancy. Serious consideration should be given to the potential hazard of its use in women of childbearing age who may become pregnant.
Diabinese is contraindicated in patients with serious impairment of hepatic, renal, or thyroid function.
Precautions: Use chlorpropamide with caution with barbiturates, in patients with Addison's disease or in those ingesting: alcohol, antibacterial sulfonamides, thiazides, phenylbutazone, salicylates, probenecid, dicoumarol or MAO inhibitors. Adequate dietary intake should be assured in all patients using Diabinese.
Warnings: DIABINESE (CHLORPROPAMIDE) SHOULD NOT BE USED IN JUVENILE DIABETES OR IN DIABETES COMPLICATED BY ACIDOSIS, COMA, SEVERE INFECTION, MAJOR SURGICAL PROCEDURES, SEVERE TRAUMA, SEVERE DIARRHEA, NAUSEA AND VOMITING, ETC. HERE, INSULIN IS INDISPENSABLE.
HYPOGLYCEMIA, IF IT OCCURS, MAY BE PROLONGED. (SEE ADVERSE REACTIONS.) IN INSTANCES OF CONCOMITANT USE WITH INSULIN, PATIENTS SHOULD BE CAREFULLY MONITORED.
Adverse Reactions: Usually dose-related and generally respond to reduction or withdrawal of therapy. Generally transient and not of a serious nature and include anorexia, nausea, vomiting and gastrointestinal intolerance; weakness and paresthesias.
Certain untoward reactions associated with idiosyncrasy or hypersensitivity have occasionally occurred, including jaundice, skin eruptions rarely progressing to erythema multiforme and exfoliative dermatitis, and probably depression of formed elements of the blood. They occur characteristically during the first six weeks of therapy. With a few exceptions, these manifestations have been mild and readily reversible on the withdrawal of the drug. The more severe manifestations may require other therapeutic measures, including corticosteroid therapy. Diabinese should be discontinued promptly when the development of sensitivity is suspected.
Jaundice has been reported, and is usually promptly reversible on discontinuance of therapy. THE OCCURRENCE OF PROGRESSIVE ALKALINE PHOSPHATASE ELEVATION SHOULD SUGGEST THE POSSIBILITY OF INCIPIENT JAUNDICE AND CONSTITUTES AN INDICATION FOR WITHDRAWAL OF THE DRUG.
Leukopenia, thrombocytopenia and mild anemia, which occur occasionally, are generally benign and revert to normal, following cessation of the drug.
Cases of aplastic anemia and agranulocytosis, generally similar to blood dyscrasias associated with other sulfonylureas, have been reported.
BECAUSE OF THE PROLONGED HYPOGLYCEMIC ACTION OF DIABINESE, PATIENTS WHO BECOME HYPOGLYCEMIC DURING THERAPY WITH THIS DRUG REQUIRE CLOSE SUPERVISION FOR A MINIMUM PERIOD OF 3 TO 5 DAYS, during which time frequent feedings or glucose administration are essential. The anorectic patient or the profoundly hypoglycemic patient should be hospitalized.
Rare cases of phototoxic reactions have been reported.
Edema associated with hyponatremia has been infrequently reported. It is usually readily reversible when medication is discontinued.
Dosage: The total daily dosage is generally taken at a single time each morning with breakfast. Occasionally, cases of gastrointestinal intolerance may be relieved by dividing the daily dosage. A LOADING OR PRIMING DOSE IS NOT NECESSARY AND SHOULD NOT BE USED. The mild to moderately severe, middle-aged, stable diabetic should be started on 250 mg daily. Because the geriatric diabetic patient appears to be more sensitive to the hypoglycemic effect of sulfonylurea drugs, older patients should be started on smaller amounts of Diabinese, in the range of 100 to 125 mg daily.
After five to seven days following initiation of therapy, dosage may be adjusted upward or downward in increments of 50 to 125 mg at intervals of three to five days. PATIENTS WHO DO NOT RESPOND COMPLETELY TO 500 MG DAILY WILL USUALLY NOT RESPOND TO HIGHER DOSES. Maintenance doses above 750 mg daily should be avoided.
Supply: 100 mg and 250 mg, blue, 'D'-shaped, scored tablets.
More detailed professional information available on request.

References: A Clue to Scholarship

References are an important part of a manuscript. Their selection is an indicator of the author's knowledge of and regard for work preceding his own, and their accuracy of recording is a clue to the quality of the author's own work. Indeed, their selection and the accuracy of their recording is a clue to the scholarship of the manuscript. This piece examines the process of selecting references, suggests a procedure to record them accurately, and describes the reasons why references are listed as they are in the AJC.

The Selection Process: Some authors tend to support statements in their manuscripts by multiple references, but often when this is done, some references do not support the statement for which they are being used. Other authors provide few references and open themselves to criticism for not giving sufficient credit to their predecessors. Should the initial or latest work on the subject be cited, or simply the present author's previous work on the subject? A clear answer to this question is lacking. A middle course between "too many" and "too few" references appears most reasonable.

A frequent criticism by reviewers of manuscripts is that their work was not cited. Accordingly, the reviewer may feel slighted and may react by being overcritical. Reference to an individual increases the chance, however, that that person will review the manuscript in question. I certainly look at the references cited when deciding to whom I will send a manuscript for review. When reading a published or unpublished paper on which they too have contributed information, many author-readers review the list of references cited. I am reminded of a story regarding 2 prominent present-day authors. William Buckley sent his most recent book to John Kenneth Galbraith, who, upon receiving it, immediately turned to the title page, anticipating a note from his friend Buckley. Finding none, Galbraith turned to the list of references and beside the first citation of one of Galbraith's books, Buckley had written, "Hi, John, Bill."

Manuscripts containing innumerable references are more likely a sign of insecurity than a mark of scholarship. It requires enormous confidence to submit a manuscript devoid of references, but references may not be necessary if the data presented is entirely new. I sometimes see manuscripts with too many references and too little data. That a publication has been read during the preparation of a manuscript is not justification for its being cited as a reference. References, in other words, should not represent a list of publications read by the author—"how much work he (she) did," so to speak. In my own manuscripts, I tend to cite about one-half to two-thirds of the publications I read in preparing the manuscript. References should be carefully selected, the references cited should in general be for quality papers, they should clearly support the statement or comment to which they are attributed; and, just as a good paragraph should have no unnecessary sentences and a good sentence no unnecessary words, a manuscript should have no unnecessary references. Each reference, like each paragraph or sentence, should have a meaningful purpose.

In the Brief Reports section of the AJC, the number of references should be limited to 6 or fewer; in Letters to the Editor, usually to 3 or fewer.

Accuracy of Recording References: Many errors are made in recording references in manuscripts. Examine any 10 references in any medical journal and usually at least 1, often more, will contain an error. Errors in references represent inadequate regard for the work of previous researchers, and I suspect that inaccurately recorded references are found most frequently in manuscripts containing inadequately recorded data. Therefore, as an editor, as well as reader, I carefully examine all references in manuscripts submitted to the AJC. Names are frequently

Continued on page A10

misspelled, initials preceding the last name are often wrong, and "Junior" or "III" occasionally are omitted. Titles often are recorded inaccurately and subtitles frequently are omitted. Volume numbers, page numbers, and year of publication often are erroneously recorded. A major source of error in citing a reference is recording a reference listed in another publication. In this situation, the error recorded in the first listing is propagated in the subsequent publication. The same careful attention should be given to references as is given to other aspects of a manuscript.

The following procedures have proved useful to me in diminishing errors in recording references for my own manuscripts.

1. Each reference initially is recorded on a 3- by 5-inch card and the writing is print rather than script to prevent subsequent misinterpretation when typed. All authors, full title with subtitle, volume, inclusive page numbers, and month and year of publication are recorded on these cards. If a reference is obtained from a previous author's reference list, a notation is made on the card that the original needs to be reviewed. The reason for recording the month of publication is that this ensures review of the original report because month of publication, of course, is not listed in published reference lists. Additionally, recording both the month and year of publication allows chronologic listing of references published in the same year on the same subject.

2. The senior or established author must check references recorded by young or relatively new investigators to ensure accuracy. Some medical institutions have librarians who check the accuracy of recorded references, but this is a luxury afforded by few medical centers or research institutions.

3. References are recorded only from the original publication. To cite a reference from a previously published reference list without checking the original publication is poor research. A medical publication should never be referenced without reading it!

4. References are *typed only once* and that is in final form in the final manuscript directly from the 3- by 5-inch cards on which they were originally recorded. The cards are numbered in pencil in the order in which they will appear. Having each reference on a separate card allows the author to change the order without altering the entire typed format.

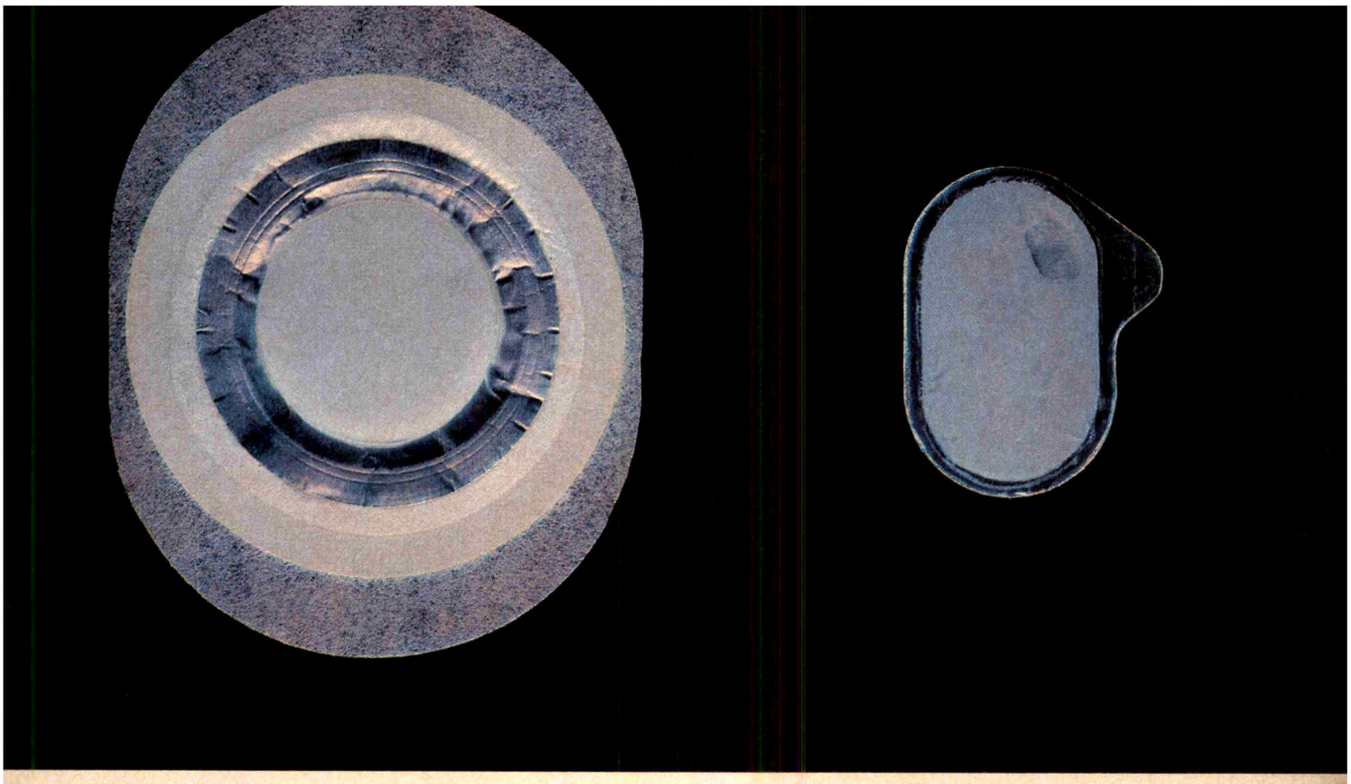
5. The typed list of references is carefully proofed from the original 3- by 5-inch reference cards by the recorder of the references on the cards. This person can read his or her own handwriting better than anyone else. More typographical errors are made in typing references than in any other portion of a manuscript. Therefore, the single typing of references from the original reference cards prevents errors which occur from multiple typings.

6. The references in the galley proofs are again checked against the original 3- by 5-inch reference cards.

Listing of References in the AJC: References listed in the AJC are complete in that the names of *all authors*, *subtitles* as well as primary titles, and *inclusive page numbers* are required. Manuscripts submitted to the AJC with references in another format suggest that the paper has been submitted previously to another journal which rejected it, or that the authors are not sensitive students of medical publications. With text pages at a premium, why are all authors, all titles, and inclusive page numbers required in the AJC? By listing all authors, all titles, and inclusive page numbers (rather than just the first page number of the article), the authors of the manuscript are virtually required to check the original article, and this checking increases the likelihood that the entire reference is recorded accurately. Supplying all authors' names allows better identification of the investigators because the last author is more often better recognized than the first author, and by having all authors listed the editor is assisted in the selection of possible manuscript reviewers. (The last author is more likely to be a member of the journal's editorial board than is the first author.) The subtitle might provide more information regarding the actual substance of a publication than the primary title. Listing inclusive page numbers prevents the confusion of a reference to a previously published manuscript with a reference to an abstract, which is never more than 1 page. To diminish the space occupied by references without diminishing their accuracy or usefulness, the type size utilized for printing references in the AJC was significantly reduced beginning in the October 1982 issue.

In summary, references are a reflection of a manuscript's quality and should be selected carefully and recorded accurately.

William C. Roberts, MD
Editor-in-Chief



The one on the left has three times more adhesive surface.

Nitro-Dur™ (nitroglycerin) Transdermal Infusion System 10cm^2, on the left, has three times the adhesive surface area of the comparable Ciba product (5 mg). Nitro-Dur 20 cm^2 provides twice the adhesive surface area as the comparable Ciba product (10 mg). The wide adhesive strip assures good matrix-to-skin contact and helps keep the system sealed and in place. It also separates easily from the backing, for easy opening and application. By contrast, the Ciba product has minimal outside adhesion. The adhesive lies primarily on the central surface through which the drug must pass.

A wide adhesive strip. It's just one reason why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

The most widely prescribed transdermal nitroglycerin system.

Please see next page for a summary of prescribing information.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release in vivo of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[1] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

INDICATIONS AND USAGE: Prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28 and hospital packs of 100.

CAUTION: Federal law prohibits dispensing without a prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

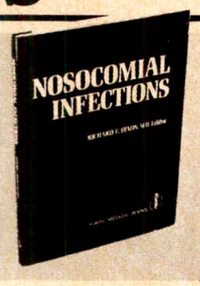
appx. 344p June 1981,
$29.50 hardbound
ISBN 0-914316-24-9
$19.50 softbound
ISBN 0-914316-29-X



Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Center for Disease Control, this book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years. This major reference is divided into 11 sections consisting of 50 chapters written by over 100 internationally known experts.

The book includes:

- An update of disease trends since the 1st International Conference held a decade earlier
- New information on the efficacy of specific approaches to infection control
- Discussions on how to implement effective infection surveillance and control programs
- Coverage of the increasing importance of antimicrobial resistance of nosocomial pathogens
- Information on the potential usefulness of antimicrobial prophylaxis in selected patient groups

and many other topics.

CONTENTS IN BRIEF

A note from the Editor-in-Chief, William C. Roberts, MD, appears on page A9 of this issue.

CORONARY HEART DISEASE

1243 **Effects of Discontinuing Maintenance Digoxin Therapy in Patients With Ischemic Heart Disease and Congestive Heart Failure in Sinus Rhythm.** Mihai Gheorghiade and George A. Beller

1251 **Efficacy and Safety of Verapamil in Patients With Angina Pectoris After 1 Year of Continuous, High-Dose Therapy.** Donald A. Weiner, Carolyn H. McCabe, Sally S. Cutler, Mark A. Creager, Thomas J. Ryan, and Michael D. Klein

1256 **Enhanced Detection of Proximal Right Coronary Artery Stenosis With the Additional Analysis of Right Ventricular Thallium-201 Uptake in Stress Scintigrams.** Jack Gutman, Michael Brachman, Alan Rozanski, Jamshid Maddahi, Alan Waxman, and Daniel S. Berman

1261 **Prognostic and Predictive Value of Exertional Hypotension in Suspected Coronary Heart Disease.** K. E. Hammermeister, Timothy A. DeRouen, Harold T. Dodge, and May Zia

1267 **Effects of a Cardioselective Beta$_1$ Partial Agonist (Corwin) on Left Ventricular Function and Myocardial Metabolism in Patients With Previous Myocardial Infarction.** Michel F. Rousseau, Hubert Pouleur, and Marie-Francoise Vincent

1275 **Relation of Segmental Wall Motion to Global Left Ventricular Function in Acute Myocardial Infarction.** Fumitaka Ohsuzu, Charles A. Boucher, John B. Newell, Tsunehiro Yasuda, Herman K. Gold, Robert C. Leinbach, Kenneth A. McKusick, Robert D. Okada, Simon Rosenthal, Gerald M. Pohost, and H. William Strauss

1282 **Effect of Metoprolol on Indirect Signs of the Size and Severity of Acute Myocardial Infarction.** Johan Herlitz, Dag Elmfeldt, Åke Hjalmarson, Stig Holmberg, Ivan Malek, Gunnar Nyberg, Lars Rydén, Karl Swedberg, Anders Vedin, Finn Waagstein, Anders Waldenström, Johan Waldenström, Hans Wedel, Lars Wilhelmsen, and Claes Wilhelmsson

1289 **Role of Myocardial Ischemia in the Genesis of Stress-Induced S-T Segment Elevation in Previous Anterior Myocardial Infarction.** Henry Gewirtz, Michael Sullivan, George O'Reilly, Steven Winter, and Albert A. Most

1294 **Enzymatic Estimation of Myocardial Infarct Size When Early Creatine Kinase Values Are Not Available.** Janet L. Smith, Dieter Ambos, Herman K. Gold, James E. Muller, W. Kenneth Poole, Daniel S. Raabe, Robert E. Rude, Eugene Passamani, Eugene Braunwald, Burton E. Sobel, Robert Roberts, and the MILIS Group

1301 **Serial Exercise Testing Up to 6 Years After Coronary Bypass Surgery: Behavior of Exercise Parameters in Groups With Different Degrees of Revascularization Determined by Postoperative Angiography.** Helmut Gohlke, Christa Gohlke-Bärwolf, Ladislaus Samek, Peter Stürzenofecker, Martin Schmuziger, and Helmut Roskamm

1307 **Cardiokymography During Exercise Testing: A New Device For the Detection of Coronary Artery Disease and Left Ventricular Wall Motion Abnormalities.** Donald A. Weiner, Carolyn H. McCabe, Gina Dagostino, Sally S. Cutler, and Thomas J. Ryan

1312 **Rest and Redistribution Thallium-201 Myocardial Scintigraphy to Predict Improvement in Left Ventricular Function After Coronary Arterial Bypass Grafting.** Abdulmassih S. Iskandrian, A-Hamid Hakki, Sally A. Kane, Inder P. Goel, Eldred D. Mundth, A-Hadi Hakki, and Bernard L. Segal, *With the technical assistance of* Angelo Amenta

SYSTEMIC HYPERTENSION

1317 **Long-Term Converting-Enzyme Inhibition as a Guide to Surgical Curability of Hypertension Associated With Renovascular Disease.** Jan Staessen, Christopher Bulpitt, Robert Fagard, Paul Lijnen, and Antoon Amery

1323 **Nifedipine Tablets for Systemic Hypertension: A Study Using Continuous Ambulatory Intraarterial Recording.** Robert S. Hornung, Brian A. Gould, Roderick I. Jones, Tansukh N. Sonecha, and Edward B. Raftery

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

1329 **Relation Between Site of Origin of Ventricular Tachycardia and Relative Left Ventricular Myocardial Perfusion and Wall Motion.** Thomas M. McFarland, David M. McCarthy, P. Todd Makler, Jr., and Mark E. Josephson

1334 **Ultrarapid Single-Capture Train Stimulation for Termination of Ventricular Tachycardia.** John D. Fisher, Eliot Ostrow, Soo Gyum Kim, and Jeffrey A. Matos

CONGESTIVE HEART FAILURE

1339 **Hemodynamic and Myocardial Performance Characteristics After Verapamil Use in Congestive Heart Failure.** Jack Ferlinz and P. Dennis Citron

1346 **Efficacy of Prazosin in the Management of Chronic Congestive Heart Failure: A 6-Month Randomized, Double-Blind, Placebo-Controlled Study.** Roy V. Markham, James R. Corbett, Alyce Gilmore, William A. Pettinger, and Brian G. Firth

1353 **Acute Hemodynamic Effects of Endralazine: A New Vasodilator for Chronic Refractory Congestive Heart Failure.** Arshed A. Quyyumi, Donald Wagstaff, and Thomas R. Evans

1358 **Exercise Intolerance in Patients With Chronic Left Heart Failure: Relation to Oxygen Transport and Ventilatory Abnormalities.** John R. Wilson and Nancy Ferraro

*Predicted theoretical service life of 10 years based on 100% dual-chamber demand (DDD) pacing at 70 ppm and delivering 0.6 ms/6 mA pulse into a 510-ohm load.

Cordis Sequicor II Technical Information

The nominal parameter values of the Sequicor II, Model 233F

Modes	DDD, DVI, DAD, VDD, VAT, VVI, DOO, VOO		
Programmed pacing rate, ppm	30 to 120 in 5-ppm increments		
Sensitivity mV (each channel)	Off, 0.5, 1.3, 2.5		
Pulse duration/ output current, ms/mA (each channel)	0.2/2 0.3/3 0.4/4	0.5/5 0.6/6 0.8/8	1.0/10 2.0/12
A-V delay, ms	75, 100, 125, 150, 175, 200, 250		
Refractory, ms (each channel)	250, 300, 350, 400, 500		
Output voltage, V (open circuit)	8 mA or higher below 8 mA	8.4 4.0	
Pace limit, ppm	160		
Battery test rates, magnet applied, ppm	70 62½ 52½	Battery satisfactory Battery nearing depletion Backup pacing (VOO) activated	
Pacing configuration	Unipolar		
Parameters revealed through telemetry	Mode, rate, sensitivity, output current, pulse duration, refractory period, and last two digits of pacer serial number.		

Specifications

Power source	Two Cordis lithium cells
Specific gravity	1.8
Weight, g	73
Thickness, mm	15
Width, mm	57
Height, mm	69
Radiopaque I.D. letters	HK

Important Information—Sequicor II

Indications and Contraindications
The medical literature describes currently accepted indications and contraindications for various pacing/sensing modes. The physician's clinical experience and judgment must ultimately be the guide in selecting the pacing mode best suited to the patient's needs.

Pacing of the ventricles (VVI) is indicated for control of heart rate in patients with A-V block or sick sinus syndrome. *Asynchronous pacing may be contraindicated for long-term pacing when inherent activity is present or is likely to be present in the chamber being paced.* There are no other known contraindications for ventricular pacing to control heart rate.

Atrial-synchronized ventricular pacing (VVD) is indicated for permanent or intermittent complete heart block with normal atrial rhythm. A-V sequential (DVI) pacing is indicated for permanent sinus bradycardia with or without heart block. Automatic dual-chamber demand pacing (DDD) is indicated when there is an A-V conduction disturbance and/or sinus node dysfunction (sinus bradycardia with A-V block or bradytachy syndrome). These atrial pacing modes are intended for patients who would benefit from the restoration of atrial contribution to cardiac output.

Atrial-synchronized ventricular pacing and automatic dual-chamber demand pacing modes are contraindicated for use in the presence of persistent atrial flutter or atrial fibrillation.

Precautions
Use Only Models 255A and 256A Cordis Programmers
Only a Cordis Model 255A Programmer III or Cordis Model 256A Interactive Programmer can be used with the Cordis Model 233F Sequicor pacer. The Sequicor II pacer *will not respond* to programming transmissions from other programmers. Do not use Cordis Models 166 and 222 Omnicor Programmers or programmers of other manufacturers.

"Use Before" Date
To assure maximum service life, pacers must be implanted before the "Use before" date shown on the package label.

Warnings
None.

Adverse Effects
A number of complications related to pacer therapy have been reported in the medical literature. The complications listed below may occur at any time after implantation.

Pacer—battery depletion, electromagnetic interference, component malfunction.

Lead—unsatisfactory electrode position, fracture, displacement, perforation of heart wall, faulty connection with pacer, migration through body tissue.

Patient—reaction, infection/erosion, increase in stimulation threshold, hemothorax, pneumothorax, embolism, thrombosis.

Read the *Instructions for Use* for more complete information prior to using.

Caution: Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

CORONARY HEART DISEASE

1243 Effects of Discontinuing Maintenance Digoxin Therapy in Patients With Ischemic Heart Disease and Congestive Heart Failure in Sinus Rhythm

MIHAI GHEORGHIADE and GEORGE A. BELLER

Twenty-four patients in sinus rhythm with ischemic heart disease and documented congestive heart failure were studied prospectively on and off maintenance oral digoxin therapy. Of these, 88% were receiving concurrent diuretics or vasodilators, or both. At 1 month off digoxin, no difference was observed in the group as a whole in heart failure score, body weight, cardiothoracic ratio, radionuclide left ventricular ejection fraction, or duration of symptom-limited treadmill exercise compared with evaluation on digoxin. By 1 month of digoxin withdrawal, the heart failure score (maximum 12 points) increased by only 1 point in 2 patients. In this study population, cessation of digoxin therapy had no adverse effects.

1251 Efficacy and Safety of Verapamil in Patients With Angina Pectoris After 1 Year of Continuous, High-Dose Therapy

DONALD A. WEINER, CAROLYN H. McCABE, SALLY S. CUTLER, MARK A. CREAGER, THOMAS J. RYAN, and MICHAEL D. KLEIN

The long-term efficacy and safety of high-dose verapamil therapy (480 mg/day) was assessed in 26 patients with chronic stable angina pectoris during a 3-phase protocol: Phase 1—an initial, 6-week placebo-controlled, double-blind crossover assessment; Phase 2—an open label, 1-year follow-up; and Phase 3—a final drug withdrawal and rechallenge 10-week study. Adverse effects during Phase 2 were mild, consisting of constipation (6 patients) and prolongation of the P-R interval (5 patients); however, no patient required alteration of the 480 mg/day dose. The clinical and exercise responses to verapamil compared with placebo were similar during the Phase 3 protocol and during the initial Phase 1 study. These investigations demonstrate that verapamil is safe and effective when evaluated after 1 year of continuous therapy in patients with chronic stable angina using a dose of 480 mg/day.

1256 Enhanced Detection of Proximal Right Coronary Artery Stenosis With the Additional Analysis of Right Ventricular Thallium-201 Uptake in Stress Scintigrams

JACK GUTMAN, MICHAEL BRACHMAN, ALAN ROZANSKI, JAMSHID MADDAHI, ALAN WAXMAN, and DANIEL S. BERMAN

The authors analyzed the accuracy of stress-induced right ventricular thallium defects for detecting proximal right coronary artery stenosis in 35 patients with and 39 without proximal right coronary artery stenosis. The sensitivity and specificity were 59 and 88%, respectively, compared with 67 and 68%, respectively, for left ventricular inferior wall thallium defects. A defect in either the right or the left ventricular inferior wall had the highest sensitivity, 93%, but a specificity of only 56%. When both ventricles had defects, all 9 patients had proximal right coronary artery stenosis; when both ventricles were normal, 26 of 28 had no proximal right coronary artery stenosis. The accuracy of exercise ventriculographic parameters (right ventricular ejection fraction and left ventricular inferior wall motion) were not significantly different. Thus, analysis of the right ventricle adds additional diagnostic information in the assessment of proximal right coronary artery stenosis.

Xanax® 0.5 mg Tablets

alprazolam C-IV

THE FIRST TRIAZOLO-BENZODIAZEPINE

Its triazolo ring gives XANAX a structure uniquely different from other benzodiazepines.

THE FIRST OF A UNIQUE CLASS

Upjohn

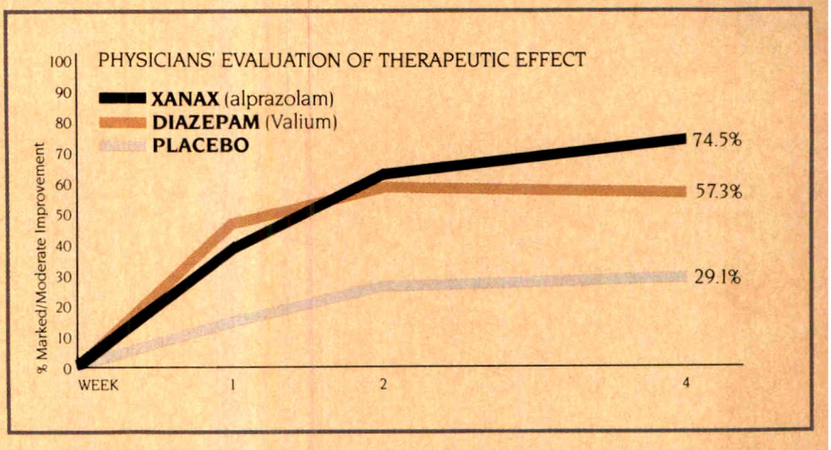
© 1982 The Upjohn Company

FOR CLINICAL ANXIETY

EFFICACY EQUAL TO DIAZEPAM WITH LESS DROWSINESS

In double-blind, placebo-controlled clinical trials in 976 patients with moderate to severe clinical anxiety, therapy with XANAX was compared to diazepam (Valium).*

Patients treated with XANAX *had a significantly lower incidence of drowsiness when compared directly to diazepam* therapy (Valium) in *a 976-patient,* placebo-controlled, multicenter study.*

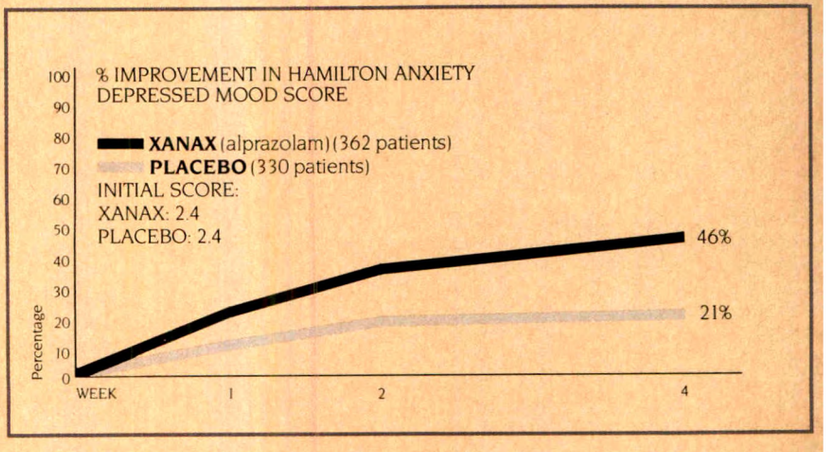


AND CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

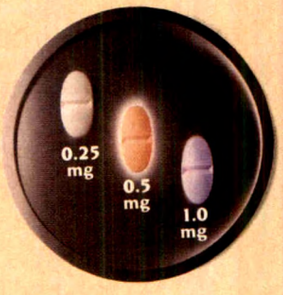
EFFECTIVE IN CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

Patients with clinical anxiety may complain of having feelings of depression, such as sadness, blueness, or loneliness.

Depressed mood is one of 14 items on the Hamilton Anxiety Rating Scale. Special analysis of 692 anxious patients with a significant depressed mood item score showed that treatment with XANAX was significantly better than placebo in decreasing depressed mood score.



SIMPLE DOSAGE: XANAX 0.25–0.5 mg T.I.D.



The usual starting dose of XANAX is 0.25 to 0.5 mg, three times daily.

Please see next page for brief summary of prescribing information.

Xanax® 0.5 mg Tablets

alprazolam

MEDICINE LIBRARY

XANAX® Tablets ©
(alprazolam)

CONTRAINDICATIONS

Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS

Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS

General: If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation (see Drug Interaction section). Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage (see Dosage and Administration). Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS

Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central Nervous System: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other Side Effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analyses are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE

Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. After prolonged therapy, dosage should be tapered. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION.

BS-1

May 1982

CARDIOLOGIST position available at the modern, multispeciality, Veterans Administration Outpatient Clinic in Sacramento, California, fully affiliated to U.C. Davis. ABIM and BC or BE in Cardiology required. Academic appointment level dependent on qualifications. Equal Opportunity Employer. Application period will close May 31, 1983. For information contact Eugen O. Grecu, M.D., Chief Medical Officer, V.A. Outpatient Clinic, 4600 Broadway, Sacramento, CA 95820 (Telephone number 916-440-2633).

PEDIATRIC CARDIOLOGY: The Department of Pediatrics at the University of Wisconsin seeks an academic cardiologist at the Associate Professor/Professor level to head section. Interest and background in teaching and investigation required. Special interest in non-invasive techniques desirable. Salary commensurate with experience. Address inquiries to:

William E. Segar, Chairman, Department of Pediatrics, H4/458 Clinical Science Center, 600 Highland Ave., Madison, WI 53792. Telephone (608) 263-8558.
The University of Wisconsin is an Equal Opportunity/Affirmative Action Employer.

CARDIOLOGIST wanted to join 3 other cardiologists. Combine teaching and private practice. Must be board certified, and have experience in all aspects of invasive and non-invasive studies. Please reply with curriculum vitae to: A. Marlon, M.D., 888 So. Rancho Drive, Las Vegas, Nevada 89106.

INVASIVE CARDIOLOGIST NEEDED IN FORT LAUDERDALE

Busy cardiology group is seeking a board certified invasive cardiologist. Must be experienced in all procedures related to cardiac catheterization: PTCA, streptokinase infusion, electrophysiological studies, and intra aortic balloon insertion. Some clinical cardiology requested.

Due to size of practice and structure of association, this is an unusual opportunity.

Please send replies to: P.O. Box 16415
Plantation, Florida 33318
c/o Lisa Davis

CONTENTS

1261 Prognostic and Predictive Value of Exertional Hypotension in Suspected Coronary Heart Disease

K. E. HAMMERMEISTER, TIMOTHY A. DeROUEN, HAROLD T. DODGE, and MAY ZIA

Late survival is impaired in patients whose blood pressure decreases during symptom-limited exercise testing compared with those whose blood pressure increases. However, the continuous variable, maximum systolic pressure during exercise, is a more powerful predictor of survival. Even though patients with exertional hypotension have more extensive coronary artery disease and more severe left ventricular dysfunction than those without, exertional hypotension is an insensitive indicator of left main coronary artery stenosis, 3-vessel disease, or severe resting left ventricular dysfunction.

1267 Effects of a Cardioselective Beta$_1$ Partial Agonist (Corwin) on Left Ventricular Function and Myocardial Metabolism in Patients With Previous Myocardial Infarction

MICHEL F. ROUSSEAU, HUBERT POULEUR, and MARIE-FRANÇOISE VINCENT

Corwin is an orally active beta$_1$ partial agonist, able to stabilize the beta$_1$ adrenoceptors at approximately 43% of their maximal activity. The hemodynamic and metabolic effects of corwin were assessed in 25 patients with a previous myocardial infarction. The data indicate that corwin is a positive inotrope, able to improve the left ventricular systolic and diastolic function without increasing myocardial oxygen consumption.

1275 Relation of Segmental Wall Motion to Global Left Ventricular Function in Acute Myocardial Infarction

FUMITAKA OHSUZU, CHARLES A. BOUCHER, JOHN B. NEWELL, TSUNEHIRO YASUDA, HERMAN K. GOLD, ROBERT C. LEINBACH, KENNETH A. McKUSICK, ROBERT D. OKADA, SIMON ROSENTHAL, GERALD M. POHOST, and H. WILLIAM STRAUSS

The relationship of left ventricular regional wall motion to global ventricular function was evaluated by radionuclide ventriculography in 127 patients within 18 hours of acute myocardial infarction. No patient had evidence of a previous infarction. The following parameters were measured: (1) wall motion index, (2) percent abnormally contracting segment, (3) ejection fraction (EF), (4) end-diastolic (EDV) and end-systolic volume (ESV), and (5) peak systolic cuff pressure/end-systolic volume ratio (PSP/ESV). The measurements of global function correlated well with wall motion index ($r = 0.83$, $p < 0.001$ for EF; $r = -0.69$, $p < 0.001$ for ESV; and $r = 0.61$, $p < 0.001$ for PSP/ESV), but EDV correlated less well ($r = -0.35$, $p < 0.001$). Multiple linear regression analysis revealed that EF correlated best with wall motion index, and no other parameter of global left ventricular function added significantly to the regression.

1282 Effect of Metoprolol on Indirect Signs of the Size and Severity of Acute Myocardial Infarction

JOHAN HERLITZ, DAG ELMFELDT, ÅKE HJALMARSON, STIG HOLMBERG, IVAN MÁLEK, GUNNAR NYBERG, LARS RYDÉN, KARL SWEDBERG, ANDERS VEDIN, FINN WAAGSTEIN, ANDERS WALDENSTRÖM, JOHAN WALDENSTRÖM, HANS WEDEL, LARS WILHELMSEN, and CLAES WILHELMSSON

In a double-blind randomized trial including 1,395 patients with suspected acute myocardial infarction (MI), the effect of the beta$_1$-selective adrenoceptor antagonist metoprolol on indirect signs of the size and severity of the infarction was evaluated. Metoprolol (15 mg) was given intravenously and followed by oral administration for 3 months (200 mg daily). Placebo was given in the same way. A lower serum enzyme activity (heat stable lactate dehydrogenase [LD] and less Q- and R-wave changes in the electrocardiogram (precordial mapping) were found in patients treated with metoprolol ≤ 12 hours after the onset of pain, whereas no difference was found in patients treated later. Patients treated with metoprolol ≤ 12 hours also showed a decreased need for furosemide, shorter duration of hospitalization, and improved 1-year survival compared with placebo, whereas no difference was found in those treated later.

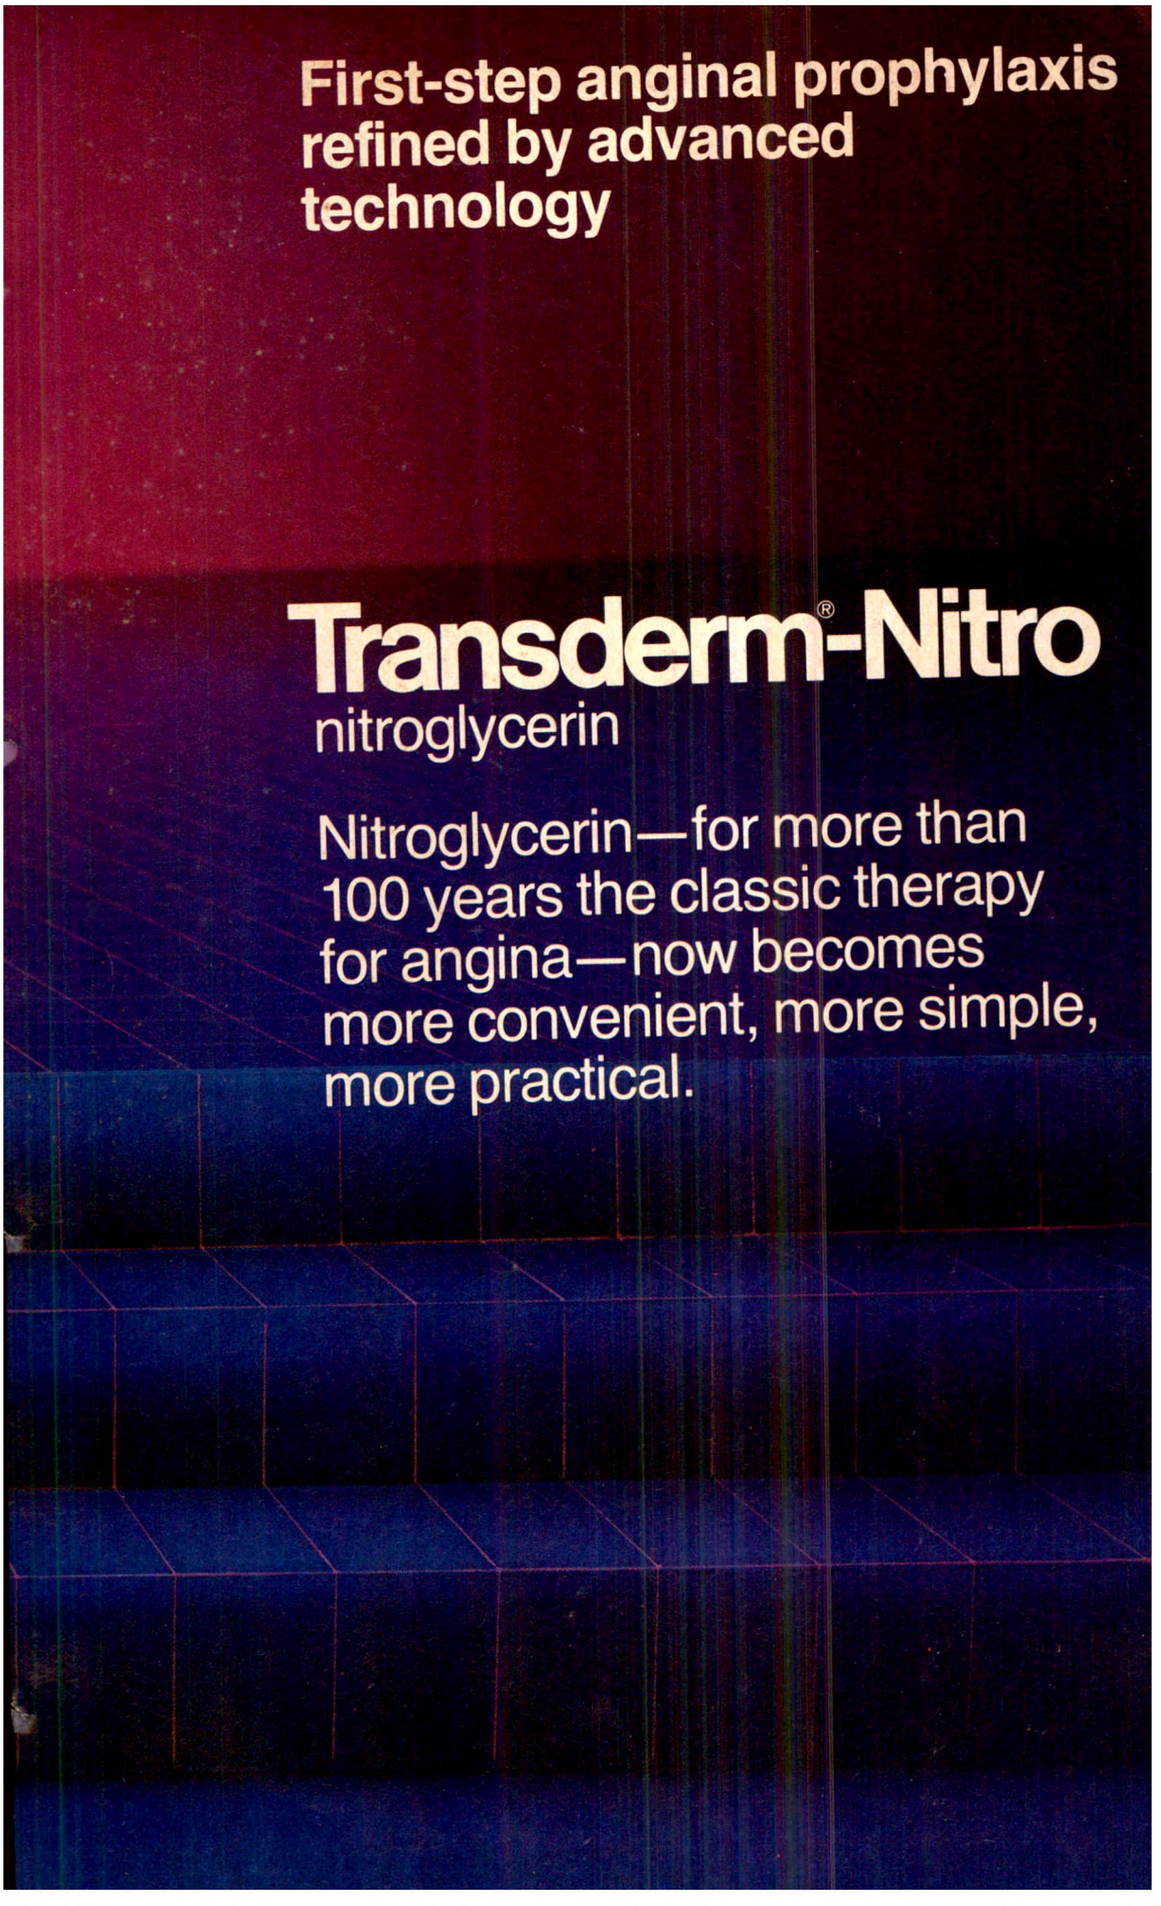
TRANSDERM NITRO 5



First-step anginal prophylaxis refined by advanced technology
Transderm®-Nitro
nitroglycerin
Nitroglycerin—for more than 100 years the classic therapy for angina—now becomes more convenient, more simple, more practical.

First-step anginal prophylaxis

Transderm®-Nitr

nitroglycerin

A step ahead of long-actin oral nitrates

"Transdermal delivery of nitroglycerin . . . overcomes th inherent problems of the oral dosage forms regarding . . . bioavailability, convenience and compliance."*

24-hour sustained therapeutic blood levels of nitroglycerin.
In contrast, so-called long-acting oral nitrates must be given in repeated doses throughout the day.

Eliminates the first-pass effect.
Unlike oral nitrates, which are predominantly inactivated in the liver, transdermal nitroglycerin bypasses the liver and enters directly into systemic circulation.

Only one simple application a day.
Avoids the inconvenience of multiple dosages.

Small, cosmetically acceptable and well tolerated.
Will not leak or stain clothing. May even be worn while bathing or swimming. Few reports of skin irritation.

Note: Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

*Black CD: Transdermal drug delivery systems. *US Pharmacist* 1982 (Nov); 7(11):49-78.

Before prescribing, please read full Prescribing Information.

C I B A

Transderm®-Nitro

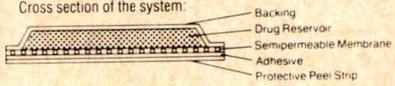
(nitroglycerin)
Transdermal Therapeutic System

DESCRIPTION
Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semi-permeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 cm^2 respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system: 0.5 mg nitroglycerin is delivered *in vivo* for every cm^2 of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface towards the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:



ACTIONS
When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

INDICATIONS AND USAGE
Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

1289 Role of Myocardial Ischemia in the Genesis of Stress-Induced S-T Segment Elevation in Previous Anterior Myocardial Infarction

HENRY GEWIRTZ, MICHAEL SULLIVAN, GEORGE O'REILLY, STEVEN WINTER, and ALBERT A. MOST

This study tests the hypothesis that myocardial ischemia is responsible for exercise-induced S-T segment elevation in patients with previous anterior myocardial infarction (MI). To accomplish this goal, exercise stress testing in conjunction with thallium imaging of the myocardium was performed in 28 such patients. Two groups of patients were identified: Group I exhibited new or increased S-T segment elevation in precordial leads V_1 to V_6 in response to stress, while Group II did not. Evidence of abnormal thallium washout from myocardial scan segments (that is, imaging evidence of ischemia) occurred in 12 of 15 Group I patients versus 9 of 13 in Group II (difference not significant). Group I patients, however, had larger anterolateral plus septal initial thallium uptake defects than did Group II patients. Similarly, resting left ventricular ejection fraction was lower in Group I than in Group II. Multiple stepwise linear regression analysis demonstrated that the extent of S-T elevation induced by stress correlated best with the size of the initial anterolateral plus septal thallium uptake defect score and to a lesser extent with resting ejection fraction and change in heart rate from rest to peak stress (corrected correlation coefficient = 0.76, $p < 0.001$). Thus, in patients with previous anterior MI, myocardial ischemia is not required for production of stress-induced S-T segment elevation. The latter likely reflects the extent of previous anterior wall damage and to a lesser extent the increase in heart rate between rest and peak stress.

1294 Enzymatic Estimation of Myocardial Infarct Size When Early Creatine Kinase Values Are Not Available

JANET L. SMITH, DIETER AMBOS, HERMAN K. GOLD, JAMES E. MULLER, W. KENNETH POOLE, DANIEL S. RAABE, Jr., ROBERT E. RUDE, EUGENE PASSAMANI, EUGENE BRAUNWALD, BURTON E. SOBEL, ROBERT ROBERTS, and the MILIS Study Group

Estimates of myocardial infarct (MI) size from plasma creatine kinase (CK) in patients admitted after the initial elevation in CK may be considerably smaller than estimates based on the total plasma CK curve. Estimates of MI size based on data inclusion intervals beginning a 24, 12, 8, and 4 hours before peak CK were 11, 14, 23, and 47% less than values based on complete CK curves. We prospectively derived correction factors from a population of 120 patients with complete, total, and MBCK time activity curves. These correction factors were then applied to a new population (n = 25) with complete CK curves to compensate for purposely omitted early CK values. The corrected estimates of MI size were within 7% of those based on the complete CK curves. Thus, if peak plasma CK is known, underestimation of MI size can be compensated for despite the unavailability of early CK values. Since 90% of patients present to the hospital before plasma CK activity has reached maximum values, MI size can be estimated in nearly all patients and is thus a more widely applicable endpoint for use in clinical trials and patient management.

1301 Series Exercise Testing Up to 6 Years After Coronary Bypass Surgery: Behavior of Exercise Parameters in Groups With Different Degrees of Revascularization Determined by Postoperative Angiography

HELMUT GOHLKE, CHRISTA GOHLKE-BÄRWOLF, LADISLAUS SAMEK, PETER STÜRZENOFECKER, MARTIN SCHMUZIGER, and HELMUT ROSKAMM

Four hundred thirty-five patients who had undergone angiography after coronary artery bypass grafting (CABG) were followed by serial exercise testing up to 6 years after CABG. One hundred eighty-two, 176, and 54 patients were completely, sufficiently, or incompletely revascularized, respectively, and 20 patients had all grafts occluded. Patients with complete revascularization showed improvement of all exercise parameters lasting for 6 years, patients with sufficient revascularization for 4 years, and patients with incomplete revascularization for 1 year only. Patients with all grafts occluded showed improvement of only some exercise parameters. The completeness of revascularization determines the extent and duration of improvement of exercise parameters.

1307 Cardiokymography During Exercise Testing: A New Device For the Detection of Coronary Artery Disease and Left Ventricular Wall Motion Abnormalities

DONALD A. WEINER, CAROLYN H. McCABE, GINA DAGOSTINO, SALLY S. CUTLER, and THOMAS J. RYAN

The cardiokymograph is a device that has been shown to reflect left ventricular wall motion abnormalities. Its accuracy in detecting coronary artery disease during treadmill exercise testing was assessed in 204 consecutive patients undergoing coronary arteriography. The sensitivity and specificity were similar for both the exercise

CardioVue™ 60 NewImage™ Phased Array

Diasonics' CV-60 is small, portable and ideal for a wide range of cardiac imaging applications.

It produces excellent, high quality images with a new, compact, wide-aperture transducer. System features include: ■ Outstanding image quality, clinical versatility and portability ■ Upgradable computer-based design ■ 50% improvement in lateral resolution ■ Multigate Doppler system capabilities.

CardioVue™ 100 Mechanical Sector Scanner

Diasonics' CV-100 is the smallest full function cardiac mechanica sector scanner available, with a proven history of upgradability and software enhancements. System features include: ■ Digital RF Ultrasound™ for superior resolution and enhanced low level echoes ■ MicroSector™ probes — smallest 16mm crystal design available ■ Pulsed and CW Doppler capabilities ■ Wide range of probes for every application.

Cardio ReVue Center

Diasonics' Cardio ReVue Center meets quantitative diagnostic requirements with: ■ Calculation/display of cardiac parameters ■ Graphics/printing/patient reports ■ User programmability ■ Digital data acquisition.

AngioVue™ DA-100

Diasonics' DA-100 produces digital images clinically equivalent to cine film, with added image manipulation and enhancement capabilities. The DA-100 provides the cath lab with advanced digi subtraction imaging and all the benefits of computerized analys ■ Totally digital coronary artery imaging ■ Quantitative ventri ulography ■ High frame rate processing/image enhancement.

AngioVue™ DXR-100

Diasonics' DXR-100 is the first standalone system for intravenous ventriculography. By combining the Diasonics/OEC 9-inch C-Arm with the Diasonics digital processor, the DXR-100 perform digital subtraction studies in or out of the cath lab. System featu include: ■ Boosted fluoro for better resolution ■ Continuous imaging at 30 fps ■ Total microprocessor system control ■ Cardiac analysis software package.

NMR Imaging

The Diasonics NMR Imaging System can simultaneously image 15 sections in 6.5 minutes with high spatial resolution and excel soft tissue contrast. With its gated imaging capability, NMR will play a major role as a diagnostic tool for the cardiovascular syst

Diasonics has filed a Pre-Market Approval application with the Food and Drug Administration. However, until approval of t application has been obtained, the Diasonics NMR Imaging System is a research device for investigational use.

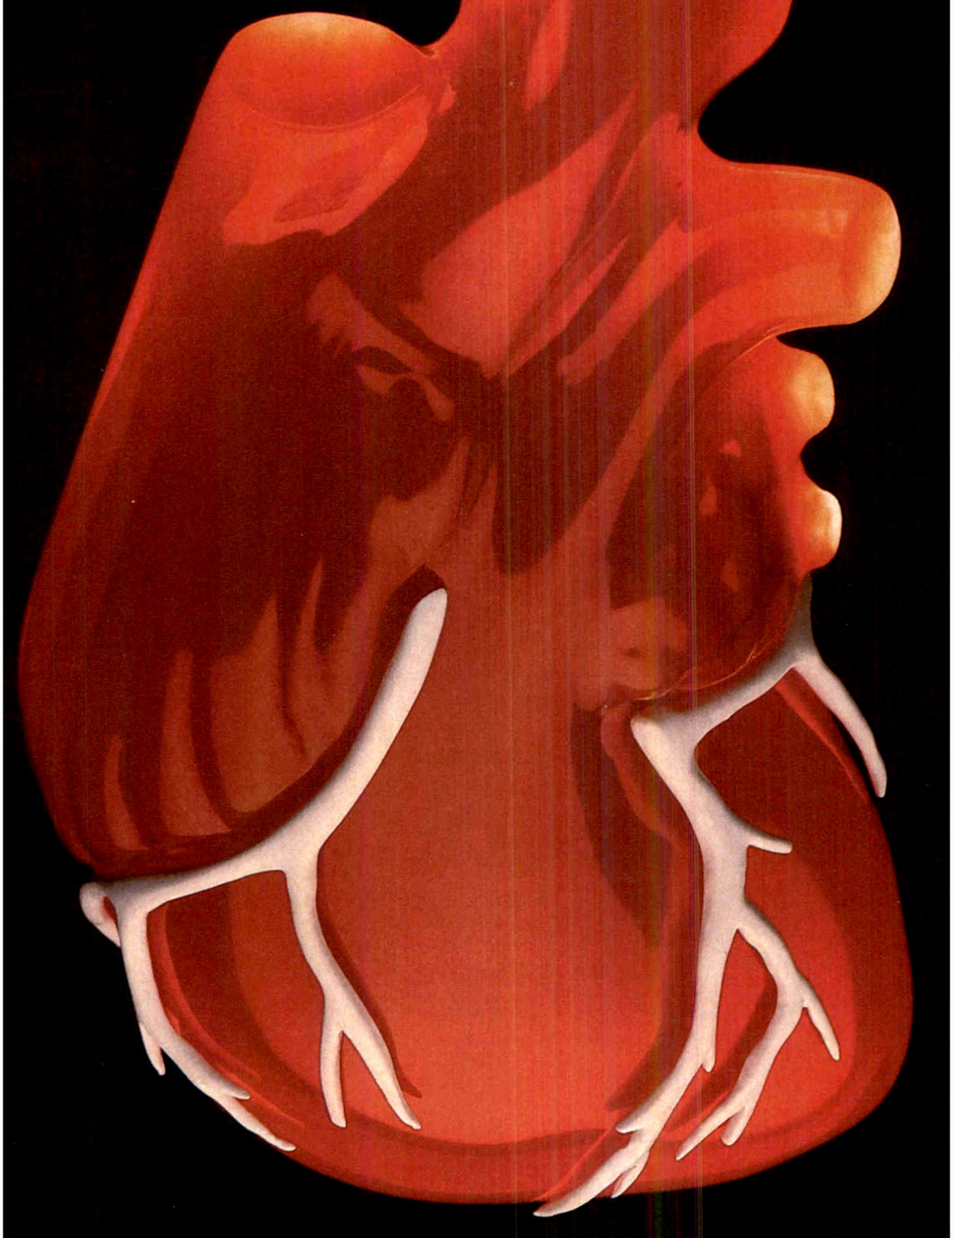
New CARDIZEM™ (diltiazem HCl)

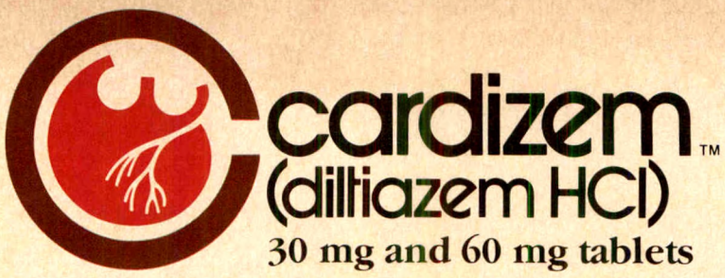
CALCIUM CHANNEL BLOCKADE

from Marion Laboratories



Potent coronary vasodilation with a distinctive hemodynamic profile

Please see full prescribing information on last



INCREASES EXERCISE TOLERANCE, REDUCES ANGINAL FREQUENCY WITH A LOW INCIDENCE OF SIDE EFFECTS

CARDIZEM™ (diltiazem HCl) produces changes in cardiovascular hemodynamics and coronary blood flow that are of benefit in myocardial ischemia.

These changes provide effective therapy with a low incidence of side effects.

Indications

(1) Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm.

(2) Cardizem is indicated in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

ANTIANGINAL MECHANISM OF ACTION

- Produces relaxation of coronary vascular smooth muscle
- Dilates both large and small coronary arteries at drug levels that cause little or no negative inotropic effect
- Produces dose-dependent decreases in peripheral resistance
- Resting heart rate is usually unchanged or slightly reduced

Reduces the pressure/rate product for any given work load in patients with effort-associated angina

© 1983, Marion Laboratories, Inc.

CARDIZEM™ (diltiazem HCl) offers a distinctive profile of effects

(1) Vascular smooth-muscle relaxation with a potent effect on the coronary arteries.[1]

(2) Mild effect on afterload reduction.

(3) In normotensive patients at rest, recommended dosage levels producing coronary vasodilation result in only a mild reduction in diastolic blood pressure and no change in heart rate.

(4) At submaximal exercise, it causes a reduction in heart rate and mean blood pressure compared with placebo, thus reducing myocardial oxygen demand and permitting patients to exercise significantly longer.

(5) Increases coronary blood flow.

(6) Little or no negative inotropic effect at recommended doses while providing a powerful inhibition of coronary artery spasm.

(7) A positive effect on left ventricular function in patients with reduced left ventricular ejection fraction.[2]

(8) Increases ejection fraction at both submaximal and maximal exercise. Exercise ejection fraction is especially increased in patients with poor ventricular function.[3]

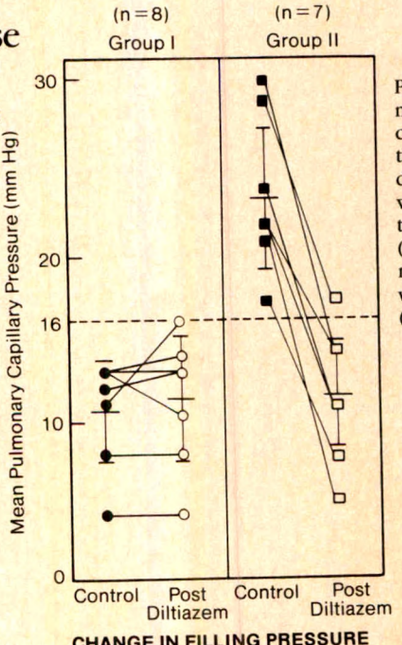
While Cardizem tends to prolong AV conduction,* only rarely has there been an increase in PR intervals outside of normal limits.

*See Contraindications and Warnings.

CARDIZEM™ (diltiazem HCl) tends to normalize stress-induced increases in pulmonary capillary pressure (PCP)

The effect of a single 120-mg† dose of Cardizem was evaluated on symptom-limited upright exercise in 15 patients with effort angina.[4]

†It should be noted that this study employed a single 120-mg dose of diltiazem for hemodynamic measurement purposes. The approved maximum dose for Cardizem is 240 mg given in divided doses, three to four times daily.



CHANGE IN FILLING PRESSURE AT MAXIMAL EXERCISE[4]

Patients with control PCPs in normal range at maximal exercise showed little change in these values following diltiazem (Group I). Patients with markedly elevated control PCPs at maximal exercise (>16 mm Hg) showed dramatic reductions in these values following diltiazem (Group II).

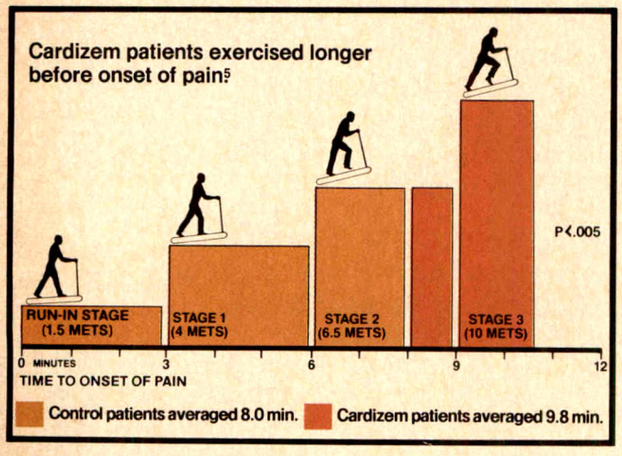
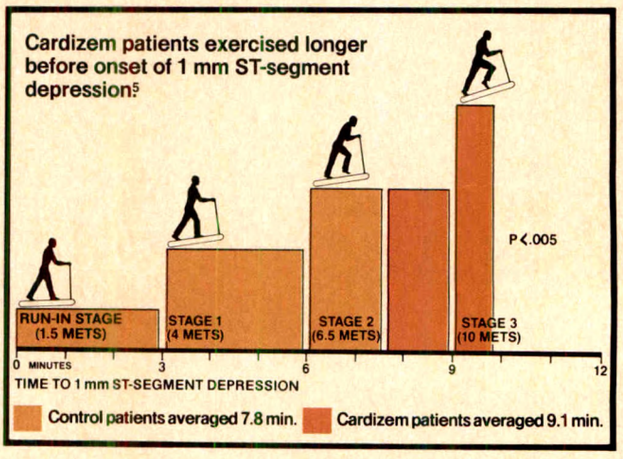
EXCELLENT CLINICAL RESPONSE TO CARDIZEM™ (diltiazem HCl) IN THE MANAGEMENT OF CLASSIC EFFORT ANGINA

CARDIZEM™ (diltiazem HCl) allows angina patients to significantly prolong exercise tolerance, even in demanding Bruce protocol exercise tests[5] (n=15)*





Protocol:

A Bruce protocol with a run-in stage was used. Each stage lasts three minutes.

Succeeding stages represent such an increase in speed and slant of the treadmill that each minute spent in a succeeding stage represents a highly significant increase in metabolic equivalents (METS). For example, METS expenditure in run-in stage of the protocol (0 to 3 min) is 1.5. METS expenditure of stage 1 (3 to 6 min) is 4.0. Stage 2 (6 to 9 min) expenditure is 6.5, and stage 3 (9 to 12 min) is 10.

The study[5,6] was double-blind, randomized, triple cross-over comparing diltiazem with placebo, lasting 7 weeks.

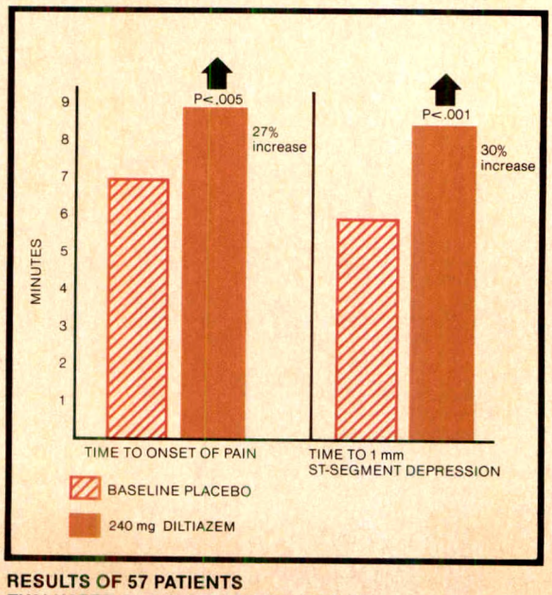
CARDIZEM™ (diltiazem HCl) produced marked angina improvement in multicenter study[6]

- 27% increase in time to onset of pain
- 30% increase in time to ST-segment depression



RESULTS OF 57 PATIENTS EVALUATED IN A MULTICENTER STUDY[6]

CARDIZEM™ (diltiazem HCl) PRODUCED SIGNIFICANT DECREASE IN EFFORT ANGINA ATTACKS COMPARED WITH PLACEBO IN 63-PATIENT DIARY STUDY[7]

Cardizem therapy resulted in a mean reduction of 5.3 attacks per week during weeks 7 and 8, compared with a mean reduction with placebo of 2.0 attacks per week.

During weeks 9 and 10, Cardizem therapy resulted in a mean reduction of approximately 5.9 attacks per week compared with a mean reduction of 2.5 attacks per week with placebo.

41% TO 68% REDUCTION IN FREQUENCY OF PRINZMETAL'S VARIANT ANGINA ATTACKS WITH CARDIZEM™ (diltiazem HCl)[8]

Mean attack rate during 120-mg/day dosage period was reduced 41% from baseline period. In 240-mg/day phase, decrease with Cardizem was 68%. This shows a positive dose-related response.

75% reduction in attack rate reported in 13-patient, cross-over, placebo-controlled study[1]

71% reduction in attack rate reported in 11-patient, cross-over, placebo-controlled study[9]

LOW INCIDENCE OF SIDE EFFECTS WITH CARDIZEM™ (diltiazem HCl)

In placebo-controlled trials conducted in the United States, the incidence of adverse reactions reported during Cardizem therapy was not greater than that reported during placebo therapy.

Those adverse reactions reported most frequently with CARDIZEM™ (diltiazem HCl) have been:

- Nausea 2.7%
- Swelling/edema 2.4%
- Arrhythmia 2.0%
- Headache 2.0%
- Rash 1.8%
- Fatigue 1.1%

In many cases, the relationship to Cardizem has not been established.

Other reactions infrequently reported (<1.0%) during supervised trials were:

- Cardiovascular: Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart
- Central Nervous System: Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations
- Gastrointestinal: Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis
- Dermatologic: Pruritus, petechiae, urticaria
- Other: Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain

Of those adverse reactions reported, the most severe were:
A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of Cardizem.

Experience in 959 patients taking oral doses of Cardizem resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

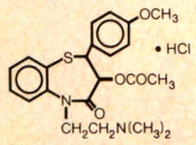
In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during Cardizem therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

PROFESSIONAL USE INFORMATION

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanism of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (4 of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem t.i.d. of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely, and enzymes were nearly normal a week after cessation of treatment. No rechallenge was carried out, but the patient had no evidence of viral hepatitis and received no other drugs but isosorbide dinitrate.

   No other similar liver injury has been reported in clinical trials, but marketing experience in Europe has resulted in a rechallenge-confirmed instance of hepatocellular injury. However, it should be noted that there have been further episodes of raised transaminases in the absence of diltiazem in this patient, so that the relationship to diltiazem of the abnormalities is not completely clear. Other instances of transaminase elevation have been reported in Europe, but their relationship to drug is uncertain.

PRECAUTIONS

General. CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect of diltiazem on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-blockers or digitalis is currently being investigated in well-controlled studies.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. Experience with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), and fatigue (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of presentation corresponds to the relative frequency of occurrence.

Cardiovascular:	Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart.
Central Nervous System:	Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations.
Gastrointestinal:	Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis.
Dermatologic:	Pruritus, petechiae, urticaria.
Other:	Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and safety of dosages exceeding 240 mg per day are currently being investigated. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents.

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

1329 Relation Between Site of Origin of Ventricular Tachycardia and Relative Left Ventricular Myocardial Perfusion and Wall Motion

THOMAS M. McFARLAND, DAVID M. McCARTHY, P. TODD MAKLER, Jr., and MARK E. JOSEPHSON

Eighteen patients with a history of recurrent sustained ventricular tachycardia underwent thallium-201 myocardial perfusion imaging and resting radionuclide ventriculography, and the results were correlated with the tachycardia site of origin (determined by endocardial mapping). All 18 patients had coronary artery disease, and 16 had left ventricular aneurysm. In most patients, the tachycardia site of origin was the periphery of a resting thallium-201 defect and the border of the aneurysm. These results help to explain the pathophysiologic aspects of this arrhythmia and provide noninvasive support for the current surgical approach in patients refractory to medical management.

1334 Ultrarapid Single-Capture Train Stimulation for Termination of Ventricular Tachycardia

JOHN D. FISHER, ELIOT OSTROW, SOO GYUM KIM, and JEFFREY A. MATOS

Some well-tolerated ventricular tachycardias can be terminated by critically timed premature pacer stimuli. Studies of such tachycardias have indicated that the termination zone for single extrastimuli begins immediately after the effective refractory period. Ultrarapid train stimulation, at 50 to 100 Hz (3,000 to 6,000 beats/min) of a duration limited to achieve only a single capture, provides the most efficient method of assuring stimulation during the termination zone. In this study single ventricular extrastimuli and ultrarapid trains were compared in 21 patients with well-tolerated ventricular tachycardia.

CONGESTIVE HEART FAILURE

1339 Hemodynamic and Myocardial Performance Characteristics After Verapamil Use in Congestive Heart Failure

JACK FERLINZ and P. DENNIS CITRON

Administration of the calcium-channel blocking agent verapamil is thought to be contraindicated in the presence of congestive heart failure (CHF) because of the drug's intrinsic negative inotropic effect. Yet, as CHF is frequently associated with arrhythmias and angina pectoris, and verapamil possesses potent antiarrhythmic and antianginal properties which could be of great benefit to selected patients with CHF, this study was undertaken to determine whether verapamil can be given to such subjects with relative safety. For this purpose, 14 patients with CHF were studied with a combined hemodynamic-cineangiographic approach before and after intravenous verapamil administration. Verapamil markedly lowered mean aortic pressure and systemic vascular resistance. Simultaneously, indexes of left ventricular performance substantially improved: ejection fraction increased from 29 ± 13 to 37 ± 17% ($p < 0.01$), and mean velocity of circumferential fiber shortening increased from 0.45 ± 0.18 to 0.64 ± 0.28 circ/s ($p < 0.001$). Therefore, the intrinsic negative inotropic activity of intravenous verapamil in therapeutic doses generally does not represent a serious drawback even in patients with CHF because its potent unloading vasodilatory properties more than compensate for any intrinsic decrease in left ventricular contractility, and can thereby actually improve overall cardiac function.

1346 Efficacy of Prazosin in the Management of Chronic Congestive Heart Failure: A 6-Month Randomized, Double-Blind, Placebo-Controlled Study

ROY V. MARKHAM, JAMES R. CORBETT, ALYCE GILMORE, WILLIAM A. PETTINGER, and BRIAN G. FIRTH

The effect of prazosin, 20 mg/day, on hemodynamic function at rest and on peak upright bicycle exercise (by radionuclide ventriculography), plasma renin activity, catecholamine levels, exercise time and work load, and standard clinical variables were assessed in 23 patients with stable class III symptoms of congestive heart failure. The study comprised a 6-month randomized, double-blind, controlled evaluation of prazosin and placebo in patients on a stable dose of digitalis and diuretics for at least 1 month. Compared with placebo, prazosin caused no demonstrable effect on symptoms of congestive heart failure, exercise time or work load, radionuclide variables, plasma renin activity, or catecholamine levels at any time. Thus, chronic prazosin therapy produced no subjective or objective improvement compared with placebo in the patients with congestive heart failure who were studied.

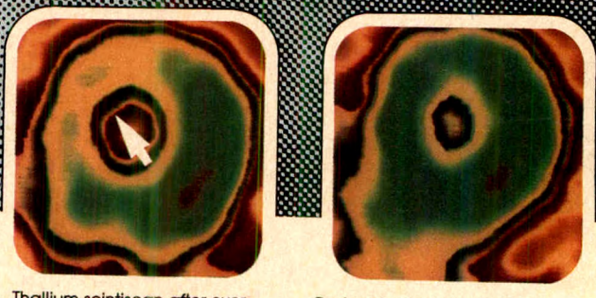
PRIORITIES IN TREATMENT OF ANXIOUS



Thallium scintiscan after exercise, showing marked anterior wall perfusion defect (arrow) before angioplasty.[1]

Postangioplasty thallium scintiscan showing no perfusion defect after peak exercise.[1]

FIRST THE BENEFITS OF PRIMARY MEASURES

Never before have physicians had so many resources for dealing effectively with cardiac disease. Now numerous cardiovascular medications are available—antianginal preparations, antihypertensives, diuretics, calcium antagonists, digitalis, quinidine, vasodilators. Besides these many agents, there are proven surgical procedures such as coronary bypass and valve replacement—and nonsurgical procedures such as angioplasty, which is fast becoming an accepted method of treating severe arterial stenoses.[1] The efficacy of angioplasty is illustrated in the above scintiscans. Yet, even with so many primary measures for improving the patient's cardiovascular status, secondary problems may adversely affect convalescence. One such problem may be excessive anxiety.[2]

SECOND THE BENEFITS OF ADJUNCTIVE ANTIANXIETY MEASURES

Anxiety in cardiac patients during recovery is a frequent response to symptoms such as chest pain, arrhythmias, breathlessness and weakness.[3] Often, anxiety can be allayed by supportive measures, such as encouraging the patient to express his fears openly, offering reassuring explanations for postcoronary symptoms and, when necessary, prescribing antianxiety medication.[3] For valid reasons, the medication often chosen is Valium® (diazepam/Roche). Its record of efficacy and safety is universally acknowledged. Little or no cardiotoxicity has been reported. Also, Valium is used with most primary cardiac medications. As with all CNS-acting agents, patients should be cautioned against drinking alcohol and against engaging in activities requiring complete mental alertness. Used judiciously, Valium can be a valuable adjunct to rehabilitative measures and can help the cardiac patient employ his own coping devices to good effect.

VALIUM®

diazepam/Roche

2-mg, 5-mg, 10-mg scored tablets

Second to none in pharmacotherapy of anxiety

Please see next page for summary of complete product information.

ROCHE®

VALIUM® (IV)
diazepam/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Management of anxiety disorders, or short-term relief of symptoms of anxiety. Anxiety or tension associated with the stress of everyday life usually does not require treatment with an anxiolytic. Symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not as sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.
The clearance of Valium and certain other benzodiazepines can be delayed in association with Tagamet (cimetidine) administration. The clinical significance of this is unclear.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. or q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

How Supplied: For oral administration, Valium scored tablets—2 mg, white; 5 mg, yellow; 10 mg, blue—bottles of 100 and 500; Prescription Paks of 50, available in trays of 10. Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10.

1353 Acute Hemodynamic Effects of Endralazine: A New Vasodilator for Chronic Refractory Congestive Heart Failure

ARSHED A. QUYYUMI, DONALD WAGSTAFF, and THOMAS R. EVANS

Invasive hemodynamic measurements were made in 10 supine patients with chronic refractory congestive heart failure (CHF) before and after oral administration of a new arteriolar vasodilator, endralazine. With the 10 mg dose, substantial afterload reduction occurred, with increases in cardiac and stroke volume indexes of 56 and 42%, respectively, and a concomitant reduction in systemic resistance. A 5 mg dose produced similar but slightly less marked changes, with a small decrease in mean arterial pressure. There were no changes in right-sided cardiac pressures. Peak effect of the drug occurred 4 hours after the dose, and the effect was maintained for 8 hours. Endralazine, a structural analog of hydralazine, has a similar hemodynamic profile, but it is free from immunologic side effects and has a smaller dose range. This makes it a useful and safe drug in the management of CHF.

1358 Exercise Intolerance in Patients With Chronic Left Heart Failure: Relation to Oxygen Transport and Ventilatory Abnormalities

JOHN R. WILSON and NANCY FERRARO

Circulatory, metabolic, and ventilatory responses to maximal and submaximal symptom-limited exercise were studied in 13 patients with chronic stable heart failure. Maximal exercise was sustained 6.5 ± 0.6 minutes (mean ± standard error of the mean) and increased minute oxygen consumption ($\dot{V}O_2$) to 940 ± 65 ml/min, whereas submaximal exercise was sustained for 15.4 ± 2.3 minutes and increased $\dot{V}O_2$ to 825 ± 49 ml/min (both $p < 0.01$ compared with maximal exercise). Both exercise protocols were terminated because of fatigue and both were associated with reduced cardiac output relative to $\dot{V}O_2$, marked systemic oxygen extraction (80 ± 2% maximal versus 78 ± 2% submaximal) and similarly elevated blood lactate concentrations (37 ± 4 mg/dl maximal versus 36 ± 4 mg/dl submaximal), suggesting inadequate oxygen delivery to working muscle. Minute ventilation during both types of exercise was also more than twice normal relative to carbon dioxide production. During submaximal exercise, dyspnea was noted in only 3 patients despite these ventilatory abnormalities. During maximal exercise, dyspnea was noted in 11 patients but did not force termination of exercise or preclude achievement of marked systemic oxygen extraction and lactate production. These data suggest that patients with chronic stable cardiac failure are limited during both maximal and submaximal exercise primarily by inadequate oxygen transport to working muscle.

1364 Hemodynamic Effects of Dibutyryl Cyclic AMP in Congestive Heart Failure

SHINOBU MATSUI, EIJI MURAKAMI, NOBORU TAKEKOSHI, JIRO EMOTO, and MUNETOSHI MATOBA

In this study the hemodynamic effects of dibutyryl cyclic AMP (DBcAMP) were evaluated in patients with congestive heart failure (CHF). In 11 patients with CHF hemodynamic variables were investigated before and after infusion of various doses of DBcAMP at a rate of 0.025 to 0.2 mg/kg/min (0.14 ± 0.077 mg/kg/min mean ± standard deviation). DBcAMP reduced total systemic vascular resistance index, pulmonary arterial end-diastolic pressure, and mean arterial blood pressure. Cardiac index and heart rate were increased. The increase in cardiac index was accompanied by a proportional decrease in total systemic vascular resistance index. Left ventricular performance was improved in 8 patients. The incremental doses of DBcAMP (0.05, 0.1, and 0.2 mg/kg/min) caused dose-related hemodynamic changes. These results suggest that DBcAMP has powerful vasodilating effects on resistance vessels in patients with CHF; hence, it can be a useful vasodilating agent for the treatment of CHF.

THERAPY

1369 Pharmacokinetic and Pharmacodynamic Effects of Diltiazem

MARK S. SMITH, CHACKO P. VERGHESE, DAVID G. SHAND, and EDWARD L. C. PRITCHETT

The pharmacokinetic and pharmacodynamic features of diltiazem were studied in 8 patients after intravenous (20 mg over 10 minutes), single oral (60 or 90 mg), and repeated oral administration (60 or 90 mg every 6 hours). Plasma levels decreased triexponentially after intravenous administration, with a half-life similar to that after oral diltiazem. The time versus concentration curve after oral diltiazem showed 2 peaks, suggesting enterohepatic recirculation. The kinetic effects or oral diltiazem were nonlinear. With repeated doses, there was significant accumulation of diltiazem and its metabolite, and there was an increase in apparent bioavailability. While minimal changes occurred in heart rate and blood pressure, there was significant prolongation of the P-R interval.

VALVULAR HEART DISEASE

1375 Prevalence of Submitral (Anular) Calcium and Its Correlates in a General Population-Based Sample (The Framingham Study)

DANIEL SAVAGE, ROBERT J. GARRISON, WILLIAM P. CASTELLI, PATRICIA M. McNAMARA, SANDRA J. ANDERSON, WILLIAM B. KANNEL, and MANNING FEINLEIB

To obtain epidemiologic information on submitral calcium, 2,069 subjects in the original Framingham Study cohort (mean age 70 ± 7 years) and 3,625 of the offspring of the cohort and their spouses (mean age 44 ± 10 years) with adequate echocardiograms were evaluated. Submitral calcium was detected in 162 (2.8%) of the 5,694 subjects; >90% of the subjects with such calcium came from the 40% of the study group >59 years of age. Women were more than twice as likely to have such calcium as men. Age in both sexes, systolic blood pressure in men, and obesity in women were significantly and independently associated with submitral calcium. There was a 12-fold excess of atrial fibrillation in subjects with (20 of 162, 12%) compared with those without (53 of 5,532, 1%) submitral calcium.

1379 Left Ventricular Volume and Ejection Fraction Response to Exercise in Aortic Regurgitation

LYNNE L. JOHNSON, ERIC R. POWERS, WESLEY R. TZALL, JANET FEDER, ROBERT R. SCIACCA, and PAUL J. CANNON

Left ventricular (LV) ejection fraction (EF) and volumes were measured at rest and peak exercise using radionuclide techniques in 27 asymptomatic and 22 symptomatic patients with aortic regurgitation (AR). In the asymptomatic AR group both end-diastolic and end-systolic volumes decreased significantly during exercise, while EF increased. In contrast, for the symptomatic group as a whole end-diastolic volume did not change and end-systolic volume increased, while EF decreased or stayed the same. Within the symptomatic group there were 2 subgroups based on volume change: 7 of 22 had a decrease in end-diastolic and end-systolic volume (a response similar to the asymptomatic group), while 8 of 22 had an increase in both end-diastolic and end-systolic volumes during exercise. These data indicate that measurements of LV volume may be useful in differentiating symptomatic patients who are able to decrease end-systolic volume during exercise from those who develop worsening LV failure during exercise.

CARDIOMYOPATHY

1386 Atrial Systole and Left Ventricular Filling in Hypertrophic Cardiomyopathy: Effect of Verapamil

ROBERT O. BONOW, TERRI M. FREDERICK, STEPHEN L. BACHARACH, MICHAEL V. GREEN, PAMELA W. GOOSE, BARRY J. MARON, and DOUGLAS R. ROSING

The contributions of rapid diastolic filling and atrial systole to left ventricular (LV) filling volume were evaluated in 30 normal volunteers and 42 patients with hypertrophic cardiomyopathy (HC) using LV time-activity curves obtained by radionuclide angiography. Although the peak rate of rapid diastolic filling was normal in 81% of HC patients, the contribution of rapid filling to LV filling volume was reduced in 45% of patients and the contribution of atrial systole was increased in 40%. During oral verapamil therapy (320 to 560 mg/day), an increased rate of rapid filling was associated with an increase in the contribution of rapid filling to LV filling volume and a decrease in the contribution of atrial systole. During verapamil, the contribution of atrial systole was above normal in only 7% of patients. These data suggest that the hemodynamic risks associated with atrial fibrillation and loss of synchronized atrial contraction may be reduced during verapamil therapy.

1392 Regression of Myocardial Cellular Hypertrophy With Vasodilator Therapy in Chronic Congestive Heart Failure Associated With Idiopathic Dilated Cardiomyopathy

DONALD V. UNVERFERTH, JOHN P. MEHEGAN, RAYMOND D. MAGORIEN, BARBARA J. UNVERFERTH, and CARL V. LEIER

Thirty-three patients completed a 3-month study on the effect of 4 drug regimens (placebo, P; isosorbide dinitrate, I; hydralazine, H; and H + I). Resting central hemodynamic variables were determined and an endomyocardial biopsy was performed at baseline and after 3 months of continuous therapy; the myocardial cell diameter

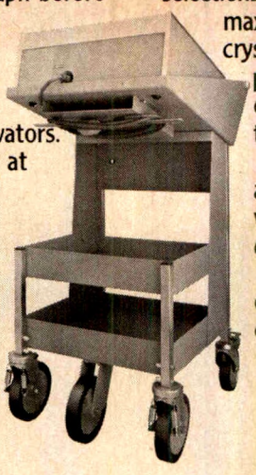
Our new fifth-wheel cart gives you exceptional ECG mobility. And if you buy a three-channel EK-670 cardiograph before May 31, 1983, Burdick will supply the cart free.

The Mobilemaster/2 cart provides sure handling through crowded hallways and easy passage between beds. And its fifth wheel helps you maneuver safely and easily in and out of elevators.

The Mobilemaster/2 also positions the EK-670 at an optimum angle for easy operation of controls and full visibility of the recording paper. Fore and aft cable connections eliminate damage from doorways and beds.

The versatile EK-670's microprocessor allows programming of the lead group combinations and lead lengths of your choice. Its four sensitivity selections on both limb and precordial leads give you maximum recording flexibility. And its four crystal-controlled paper speeds provide minimum paper usage. The EK-670 can also be a key component of Burdick ExTOL™ exercise tolerance testing systems.



Whatever the application, you'll get one-button automatic recording of standard ECGs on wide-paper format with ample space for patient data. No mounting required.

Find out more about our free Mobilemaster/2 offer and the many other EK-670 advantages. Call or write for information today.

There's a big advantage to buying an EK-670 now.

The cart is free.

Don't miss this special offer from Burdick.

for many post-MI patients...

Cardio-protective.

Cardioprotective is a word you won't find in standard medical dictionaries.

But you will find it appearing in the medical literature. And you will be hearing it in medical discussions. Until dictionaries recognize the term, MSD invites you to use this as a working definition of *cardioprotective:*

"reduction of the risk of reinfarction and cardiac mortality for many stabilized post-MI patients."

We at MSD feel it is appropriate to bring you this definition of cardioprotective since it was MSD that brought you the impressive clinical data[1] that documented the cardioprotective benefits of BLOCADREN® (Timolol Maleate, MSD) for many stabilized patients who have survived the acute phase of a myocardial infarction.

[1]The Norwegian Multicenter Study Group: Timolol-induced reduction in mortality and reinfarction in patients surviving acute myocardial infarction, N. Engl. J. Med. 304(14):801-807, April 2, 1981.

BLOCADREN is contraindicated in patients with bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

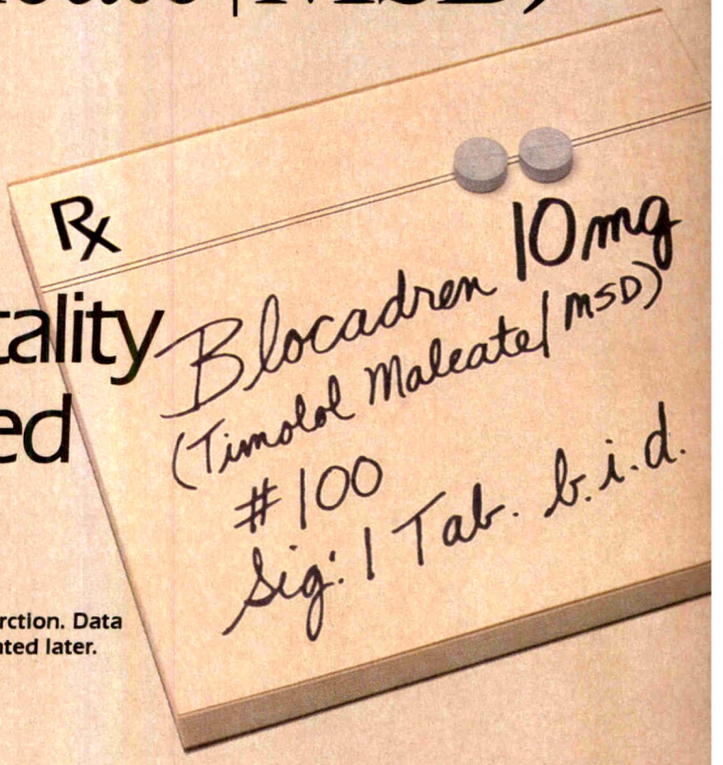
Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated.

In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after abrupt discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart

Blocadren®
(Timolol Maleate | MSD)

reduces the risk of reinfarction and cardiac mortality for many stabilized post-MI patients



Treatment should be initiated within 1 to 4 weeks after infarction. Data are not available as to whether benefit would ensue if initiated later.

disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

MSD
MERCK SHARP & DOHME

For a Brief Summary of Prescribing Information, please see next page of this advertisement.

BLOCADREN®
(TIMOLOL MALEATE | MSD)

CONTRAINDICATIONS:

Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: Impaired Hepatic or Renal Function: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy—Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n=176) %	Placebo (n=168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
INTEGUMENTARY		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction†		Withdrawal‡	
	Timolol (n=945) %	Placebo (n=939) %	Timolol (n=945) %	Placebo (n=939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure—Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema—Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1
AV Block 2nd or 3rd degree	<1	<1	<1	<1
Sinoatrial Block	<1	<1	<1	<1
Cold Hands and Feet	8	<1	<1	0
Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

†When an adverse reaction recurred in a patient, it is listed only once.

‡Only principal reason for withdrawal in each patient is listed.

These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole*: extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular*: cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness; *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes; *Urogenital*: impotence, urination difficulties.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS); *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

of 50 cells per biopsy was measured. The P group had no change in any measurements. The I and H + I groups had a significant decrease in pulmonary capillary wedge pressure and pulmonary vascular resistance. The H and H + I groups had a significant increase in cardiac index and a decrease in systemic vascular resistance and myocardial cell diameter. Chronic therapy of heart failure with I or H + I results in a persistent decrease in preload; chronic therapy with H and H + I effects a persistent augmentation in systolic function, a decrease in afterload, and an improvement in myocardial cellular morphology.

METHODS

1399 Comparison of Digital Intravenous Ventriculography With Direct Left Ventriculography for Quantitation of Left Ventricular Volumes and Ejection Fractions

SHARON L. NORRIS, ROBERT A. SLUTSKY, G. B. JOHN MANCINI, WILLIAM L. ASHBURN, GABRIEL GREGORATOS, KIRK L. PETERSON, and CHARLES B. HIGGINS, *With the technical assistance of* ELLEN EINSIDLER and WESLEY DILLON

Digital images of the left ventricle after central venous injection of contrast medium (digital intravenous ventriculography) were used to estimate left ventricular volumes and ejection function and compared with direct ventriculograms. Both end-diastolic volume ($r = 0.88$) and end-systolic volume ($r = 0.89$) correlated closely between the 2 techniques. Combining end-diastolic and end-systolic volume to define the relations between the 2 techniques yielded a high correlation ($r = 0.96$). It is concluded that area-length estimates of left ventricular volumes and ejection fraction can be accurately obtained from digital processing of fluoroscopic left ventricular images after intravenous injection of contrast medium.

1404 Regional Distribution of Pulmonary Blood Volume: An Index of Pulmonary Capillary Wedge Pressure Determined From Blood Pool Scintigraphy

TIMOTHY M. BATEMAN, RICHARD J. GRAY, LAWRENCE S. C. CZER, RONALD L. LEVY, MORGAN E. STEWART, MICHELE A. DeROBERTIS, DAVID E. BROWN, JACK M. MATLOFF, H. J. C. SWAN, and DANIEL S. BERMAN

Progressive redistribution of pulmonary blood flow to the lung apices occurs with increasing degrees of left ventricular failure. This study, using technetium-99m equilibrium blood pool scintigraphy, demonstrates that similar changes occur in the distribution of pulmonary blood volume, and correlates progressive changes in pulmonary blood volume toward the apex with progressive changes in pulmonary capillary wedge pressure (PCWP). Thirty patients being monitored with pulmonary artery balloon flotation catheters underwent imaging at the same time as PCWP determination. PCWP was compared with the average radioactive count density arising from apical (A) and basal (B) regions of interest within the right lung, expressed as an A/B ratio. Correlation between A/B and PCWP was strong for patients imaged erect in either the posterior ($r = 0.864$, $p = 0.001$) or left anterior oblique 45° position ($r = 0.842$, $p = 0.001$), and only slightly less so for patients imaged supine ($r = 0.678$, $p = 0.001$). Especially when imaging was performed with patients erect, an A/B ratio greater than unity identified with high sensitivity (100%) and specificity (83 to 88%) an abnormally elevated PCWP (>12 mm Hg). Moreover, directional changes in the A/B ratio reflected concomitant changes in PCWP after intervention. Thus, analysis of lung A/B radioactive count ratios obtained by equilibrium blood pool scintigraphy may be used to estimate PCWP.

EXPERIMENTAL STUDIES

1409 Sustained Limitation of Myocardial Necrosis 24 Hours After Coronary Artery Occlusion: Verapamil Infusion in Dogs With Small Myocardial Infarcts

DEREK M. YELLON, DAVID J. HEARSE, MILES P. MAXWELL, DAVID E. CHAMBERS, and JAMES M. DOWNEY

Studies were undertaken to ascertain whether verapamil infusion affords a sustained limitation of myocardial injury in the dog after a 24-hour period of coronary artery occlusion. Immediately after embolization radioactive microspheres were administered intraventricularly to define any area of myocardial underperfusion (zone at risk of infarction). Verapamil (0.005 mg/kg/min) was then administered and maintained for 24 hours during which time the dogs were allowed to recover from anesthesia. After 24 hours the dogs were killed and transverse myocardial sections (3 cm) were prepared. The resulting area of necrosis was visualized by tetrazolium staining, and

Versatrax™ II Model 7000A Universal A-V Pacemaker

Intended Use

The Model 7000A universal A-V pulse generator has a wide range of application in patients requiring permanent cardiac pacing where restoration of A-V synchrony and/or sinus modulated rate variability is indicated to improve cardiac output or to protect against arrhythmias related to the sequence of cardiac impulse propagation.

With the Model 7000A programmed in the A-V universal (DDD) mode, indications may include:

- Some of the sick sinus syndrome conditions such as intermittent sinus bradycardia, sinus arrest or SA block.
- Intermittent or complete atrioventricular block with normal sinus activity.
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V interval settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

In the A-V sequential (DVI) mode, the Model 7000A may have application in the following:

- Sick Sinus Syndrome (sinus bradycardia, sinus arrest, SA block, and the brady-tachy syndrome).
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V delay settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

At any time, the Model 7000A can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry (e.g., atrial lead malfunction).

NOTE: The Medtronic® Model 7000A universal A-V pulse generator is under clinical investigation in the U.S. The procedures for using this pulse generator, as well as its safety and efficacy, will be evaluated during this investigational study according to the Clinical Investigation Protocol. Therefore, the "Intended Uses" section is based on Medtronic's experience with other physiologic pulse generators. No claims for safety and efficacy can be made for the Model 7000A pulse generator during its clinical investigation. Patients should be advised that the Model 7000A pulse generator is under clinical investigation.

Contraindications

General: There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician.

DDD Mode: The DDD mode is contraindicated in the presence of atrial fibrillation, atrial flutter and rapid atrial rhythms or slow retrograde conduction.

DVI Mode: In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation or flutter.

Warnings

Diathermy: Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site.

Electrosurgical Units: Electrosurgical units should never be used in the vicinity of unipolar pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead.

Defibrillation: Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. Positioning a magnet or the programming head over the pulse generator makes it subject to programming. A nominal vertical magnetic field strength of 90 Gauss (in a field measured 1½ inches from the magnet's surface) from a magnet at 1¼ inches from the reed switch is required to initiate asynchronous pacing. Do not use electrocautery, diathermy, or any other source of electromagnetic interference in the vicinity of the patient once a magnet or programming head has been positioned over the pulse generator. If an electrocautery unit is used, the physician may prefer to program the pacemaker to asynchronous pacing prior to the procedure.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

risk zones were visualized by autoradiography. In the control heart, 62 ± 7% of the zone at risk deteriorated to necrotic tissue, whereas in the verapamil-treated group only 18 ± 4% of the tissue in the zone at risk became necrotic. Verapamil thus exerted a significant ($p < 0.001$) tissue-sparing effect that was sustained at least 24 hours after the onset of ischemia.

1414 Diastolic Synchronized Retroperfusion Versus Reperfusion: Effects on Regional Left Ventricular Function and Myocardial Blood Flow During Acute Coronary Occlusion in Dogs

JEAN C. FARCOT, ALAIN BERDEAUX, JEAN F. GIUDICELLI, JEAN P. VILAINE, and JEAN P. BOURDARIAS

The authors investigated the effects of 170 minutes of diastolic synchronized retroperfusion of the coronary sinus with arterial blood during 180 minutes of coronary artery occlusion on regional myocardial contractility (ultrasonic crystals) and blood flow (microspheres) in open-chest dogs. These effects were compared with those of 180 minutes of coronary occlusion and 170 minutes of anterograde reperfusion after 10 minutes of coronary occlusion in separate groups of dogs. Retroperfusion was able to almost restore transmural blood flow in the moderately ischemic zones and to raise it back to 47% of its preocclusion value in the severely ischemic zones with, in both zones, a favorable redistribution of flow toward the endocardium. Simultaneously, retroperfusion significantly improved segment length shortening in the moderately ischemic zones and significantly reduced the extent of paradoxical bulging in the severely ischemic zones. These partial recoveries in regional contractility and blood flow during retroperfusion were intermediate between those induced by 170 minutes of anterograde reperfusion and those of 180 minutes of coronary artery occlusion. Thus, in the presence of coronary artery occlusion, retroperfusion appears to exert a beneficial effect by improving both regional perfusion and function in the ischemic zones and may be proposed as a medical circulatory support to the jeopardized myocardium.

1422 Effects of Ortho-Iodo Sodium Benzoate on Acute Myocardial Ischemia, Hemodynamic Function, and Infarct Size After Coronary Occlusion in Dogs

ROBERT E. RUDE, JOHN TUMAS, MARCEL GUNST, ROBERT A. KLONER, LAURENCE W. V. DeBOER, and PETER R. MAROKO

Effects of ortho-iodo sodium benzoate (OISB), which decreases the affinity of hemoglobin for oxygen, thus enhancing potential tissue oxygen delivery, were tested in anesthetized dogs undergoing left anterior descending coronary artery (LAD) occlusion. Intravenous OISB reduced epicardial S-T segment elevation 15 minutes after LAD occlusion, while normal saline solution did not affect this index of ischemia. In 34 dogs, infarct size was assessed after death or killing 8 to 24 hours after LAD occlusion, and was 29% less in dogs that had received OISB before LAD occlusion. In a third group, OISB infusion 15 minutes after LAD occlusion decreased epicardial S-T segment elevation as well as heart rate, left ventricular dP/dt, and cardiac output, while a similar volume of normal saline solution had no effect on these variables. Thus, both acute myocardial ischemic injury and ultimate infarct size are reduced when OISB is infused before occlusion, and OISB also reduces ischemic injury when its administration is begun 15 minutes after LAD occlusion.

1428 Relation of Immediate and Delayed Thallium-201 Distribution to Localization of Iodine-125 Antimyosin Antibody in Acute Experimental Myocardial Infarction

BAN AN KHAW, WILLIAM STRAUSS, GERALD M. POHOST, JOHN T. FALLON, HUGO A. KATUS, and EDGAR HABER

Thallium-201 (Tl-201) is believed to be taken up by viable myocardium. Therefore, T1-201 distribution in acute experimental myocardial infarction was compared with cardiac-specific antimyosin Fab (AM-Fab) localization, a specific marker of myocyte necrosis, and with relative microsphere-determined regional myocardial blood flow. Our study showed that immediate (5 minutes) T1-201 distribution in experimental myocardial infarction is directly proportional to regional blood flow ($r = 0.971$) but is inversely exponentially related to iodine-125–AM-Fab uptake. On the other hand, delayed T1-201 distribution showed an inverse linear relation to AM-Fab uptake ($r = -0.935$ and -0.828). These relationships indicated that early T1-201 distribution reflected regional blood flow, whereas delayed T1-201 distribution demarcated viable myocardium, which is confirmed by the lack of AM-Fab uptake.

A THERAPEUTIC STEP AHEAD

LOPID®
(gemfibrozil)

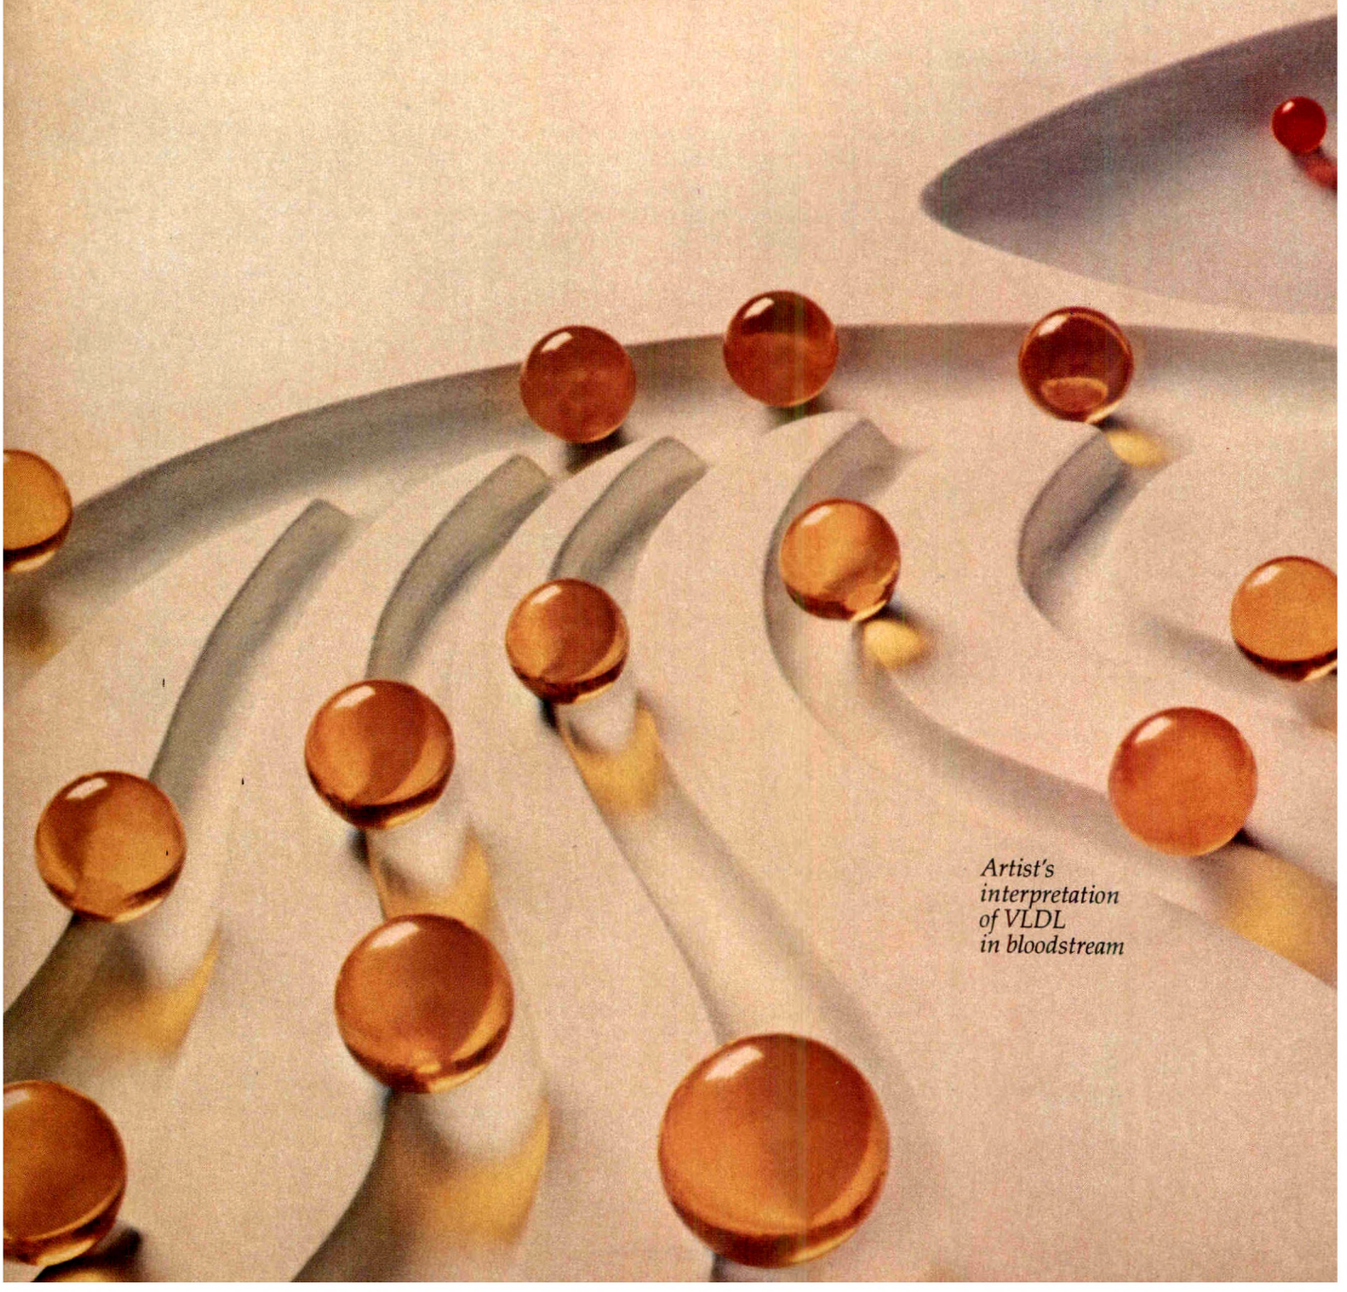
MORE THAN A LIPID-LOWERING AGENT— A TWO-WAY LIPID REGULATOR

Favorably regulates the balance of lipid fractions in certain dyslipidemias:

1/LOWERS elevated serum levels of triglyceride-rich VLDL and, to a lesser extent cholesterol-rich LDL (very-low- and low-dens lipoproteins implicated in dyslipidemia)

2/May also RAISE serum levels of HDL (high-density lipoproteins believed to transpo cholesterol to the liver for catabolism and excretion)

LOPID is indicated for treatment of adult patients with very high serum triglyceride leve (type IV hyperlipidemia) who present a risk of pancreatitis and who do not respond adequately to diet.

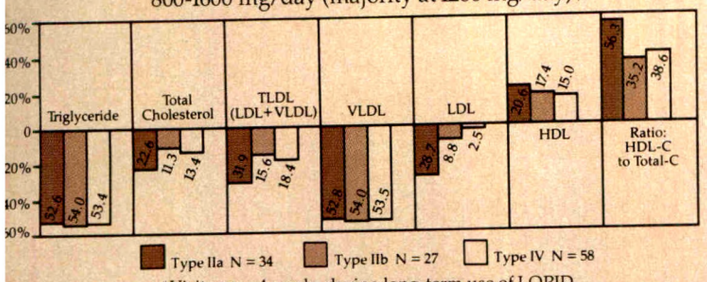


Artist's interpretation of VLDL in bloodstream

Lipid-regulating efficacy demonstrated in 1,437 patients with dyslipidemia[1]

Results of open-label phase of US multicenter study (119 patients) at end of 12 lunar months*

Average % change from baseline at doses ranging from 800-1600 mg/day (majority at 1200 mg/day)†



*Visit every 4 weeks during long-term use of LOPID.

†Data cited on this graph reflect clinical experience based on the multicenter trial. They do not imply an indication for Types IIa and IIb dyslipidemias.

Well tolerated, well accepted in clinical trials[1]

Profile of side effects similar to that of placebo.

No significant abnormalities seen in clinical and laboratory evaluations.

Less than 1% patient dropout in largest US study.

Convenient BID dosage

Diet, exercise, and weight loss are the first choice in therapy of lipid disorders.

LOPID®
(gemfibrozil)
A LIPID REGULATOR

LOPID® (gemfibrozil) Capsules

Before prescribing, please see full prescribing information.
A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO: HDL Cholesterol / Total Cholesterol
		Total	VLDL	LDL	HDL	
IIa	−44%	−4.2%	−44.3%	−5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	−6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (See WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis—LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy**—Before instituting LOPID (gemfibrozil) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy**—Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Seasonal Variation of Lipid Levels**—LOPID is not expected to alter seasonal variations of higher serum lipid values in mid-winter and late summer or the lower values in fall and spring.

4. **Impairment of Fertility**—Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. **Liver Function**—Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. **Cardiac Arrhythmias**—Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria
Central Nervous System: headache, dizziness, blurred vision
Musculoskeletal: painful extremities
Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia
Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints
Central Nervous System: vertigo, insomnia, paresthesia, tinnitus
Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)
Miscellaneous: fatigue, malaise, syncope

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

1433 Nature of "Residual Fast Channel" Dependent Action Potentials and Slow Conduction in Guinea Pig Ventricular Muscle and Its Modification by Isoproterenol

MAKOTO ARITA, TATSUTO KIYOSUE, MASAHIRO AOMINE, and SUNAO IMANISHI

The nature of "residual fast channel" dependent action potentials and conduction was studied in guinea pig ventricular papillary muscle in which the resting potential was reduced to 58 ± 1 mV in high K^+ (16.7 m*M*) Tyrode's solution, with or without isoproterenol (0.1 μM). In the absence of isoproterenol, the action potential had a slur on the upstroke and the maximum rate of rise ($\dot{V}_{max}$) was composed of 2 separable peaks: the early large (32 ± 7 V/s, $\dot{V}_{max,fast}$) and the late small (10 ± 2 V/s, $\dot{V}_{max,slow}$) ones. Conduction velocity ranged from 30 to 35 cm/s. $\dot{V}_{max,fast}$ was selectively depressed by tetrodotoxin (1 μM) and $\dot{V}_{max,slow}$ by l-verapamil (1 μg/ml), indicating that the impulses were transmitted through incompletely inactivated ("residual") fast channels. Lidocaine (2 μg/ml) depressed $\dot{V}_{max,fast}$ with reduction of conduction velocity to about 20 cm/s just before the conduction block. Isoproterenol quadrupled $\dot{V}_{max,slow}$ but decreased $\dot{V}_{max,fast}$. As a result, the $\dot{V}_{max,slow}$ overrode the $\dot{V}_{max,fast}$ without change in the conduction velocity. Isoproterenol produced rate-dependent shortening in action potential duration with rate-independent shortening of postexcitation refractoriness, thereby resulting in a significant shortening in the effective refractory period at faster rates (0.5 and 0.9 Hz). Results suggest that the "residual fast channel" could produce "slow conduction" and that the ionic channels (fast or slow) responsible for the slow conduction may alternate according to local concentrations of tissue catecholamines.

1441 Vessel Wall Arachidonate Metabolism After Angioplasty: Possible Mediators of Postangioplasty Vasospasm

ANDREW CRAGG, STANLEY EINZIG, WILFRIDO CASTANEDA-ZUNIGA, KURT AMPLATZ, JAMES G. WHITE, and GUNDU H. R. RAO

Vasospasm is a serious complication of angioplasty. The investigators postulated that arterial dilatation might interfere with vessel wall arachidonate metabolism and thus predispose the vessel to spasm. They found that balloon angioplasty of canine carotid arteries significantly impaired local production of the vasodilating prostaglandins PGI_2 and PGE_2 while augmenting production of the lipoxygenase product of arachidonate metabolism, 12L-hydroperoxy-5,8,10,14-eicosatetraenoic acid (HPETE), a potent vasoconstrictor. Thus, damage to the vessel wall during angioplasty alters local arachidonic acid metabolism and may contribute to vasospasm in certain cases.

1446 Cryosurgery of the Fetal Ductus Arteriosus

PAGE A. W. ANDERSON, FREDERICK B. ASKIN, and MARCOS J. PUPKIN

Cryosurgery of the fetal ductus arteriosus, a new approach to altering the function of the neonatal ductus arteriosus, is assessed. Cryosurgical treatment was performed in 5 fetal lambs (gestational age 127 ± 8 days ± 1 standard deviation) and sham treatment in 6 fetal lambs (gestational age 128 ± 5 days). After birth, all the cryotreated lambs had a patent ductus arteriosus while all the control lambs had a closed ductus arteriosus. Histologic evaluation demonstrated the media of the cyotreated ductus arteriosus to have calcification, bland necrosis, and ganglion cell necrosis. These findings suggest that cryosurgery may be a useful technique for maintaining ductus arteriosus patency.

1451 Coronary Constriction by Leukotriene C_4, D_4, and E_4 in the Intact Pig Heart

DAVID EZRA, LILLIE BOYD, GIORA FEUERSTEIN, and ROBERT E. GOLDSTEIN

Leukotrienes are vasoactive metabolites of arachidonic acid that increase during inflammatory reactions and anaphylaxis. To test effects of leukotriene C_4, D_4, and E_4 on coronary vessels, coronary blood flow, arterial pressure, left ventricular end-diastolic pressure, and heart rate were measured after bolus injection of 0.1 to 3 μg of each leukotriene into a coronary artery in 8 open-chest pigs. Each leukotriene produced a marked, dose-related decrease in coronary blood flow within 30 seconds of injection. Three micrograms of each leukotriene produced the following maximal decreases: $C_4 = 80 \pm 9\%$, $p < 0.001$; $D_4 = 81 \pm 3\%$, $p < 0.001$; $E_4 = 64 \pm 12\%$ $p < 0.005$. In several instances electrocardiographic signs of focal myocardial ischemia were recorded. Significant elevation of left ventricular end-diastolic pressure was observed after the large doses (1.0 and 3.0 μg) of leukotriene C_4 and D_4. This study shows that leukotrienes are extremely potent coronary constrictors for the in situ heart. This action may have deleterious consequences on myocardial perfusion when inflammatory processes and anaphylaxis lead to increased production of leukotrienes.

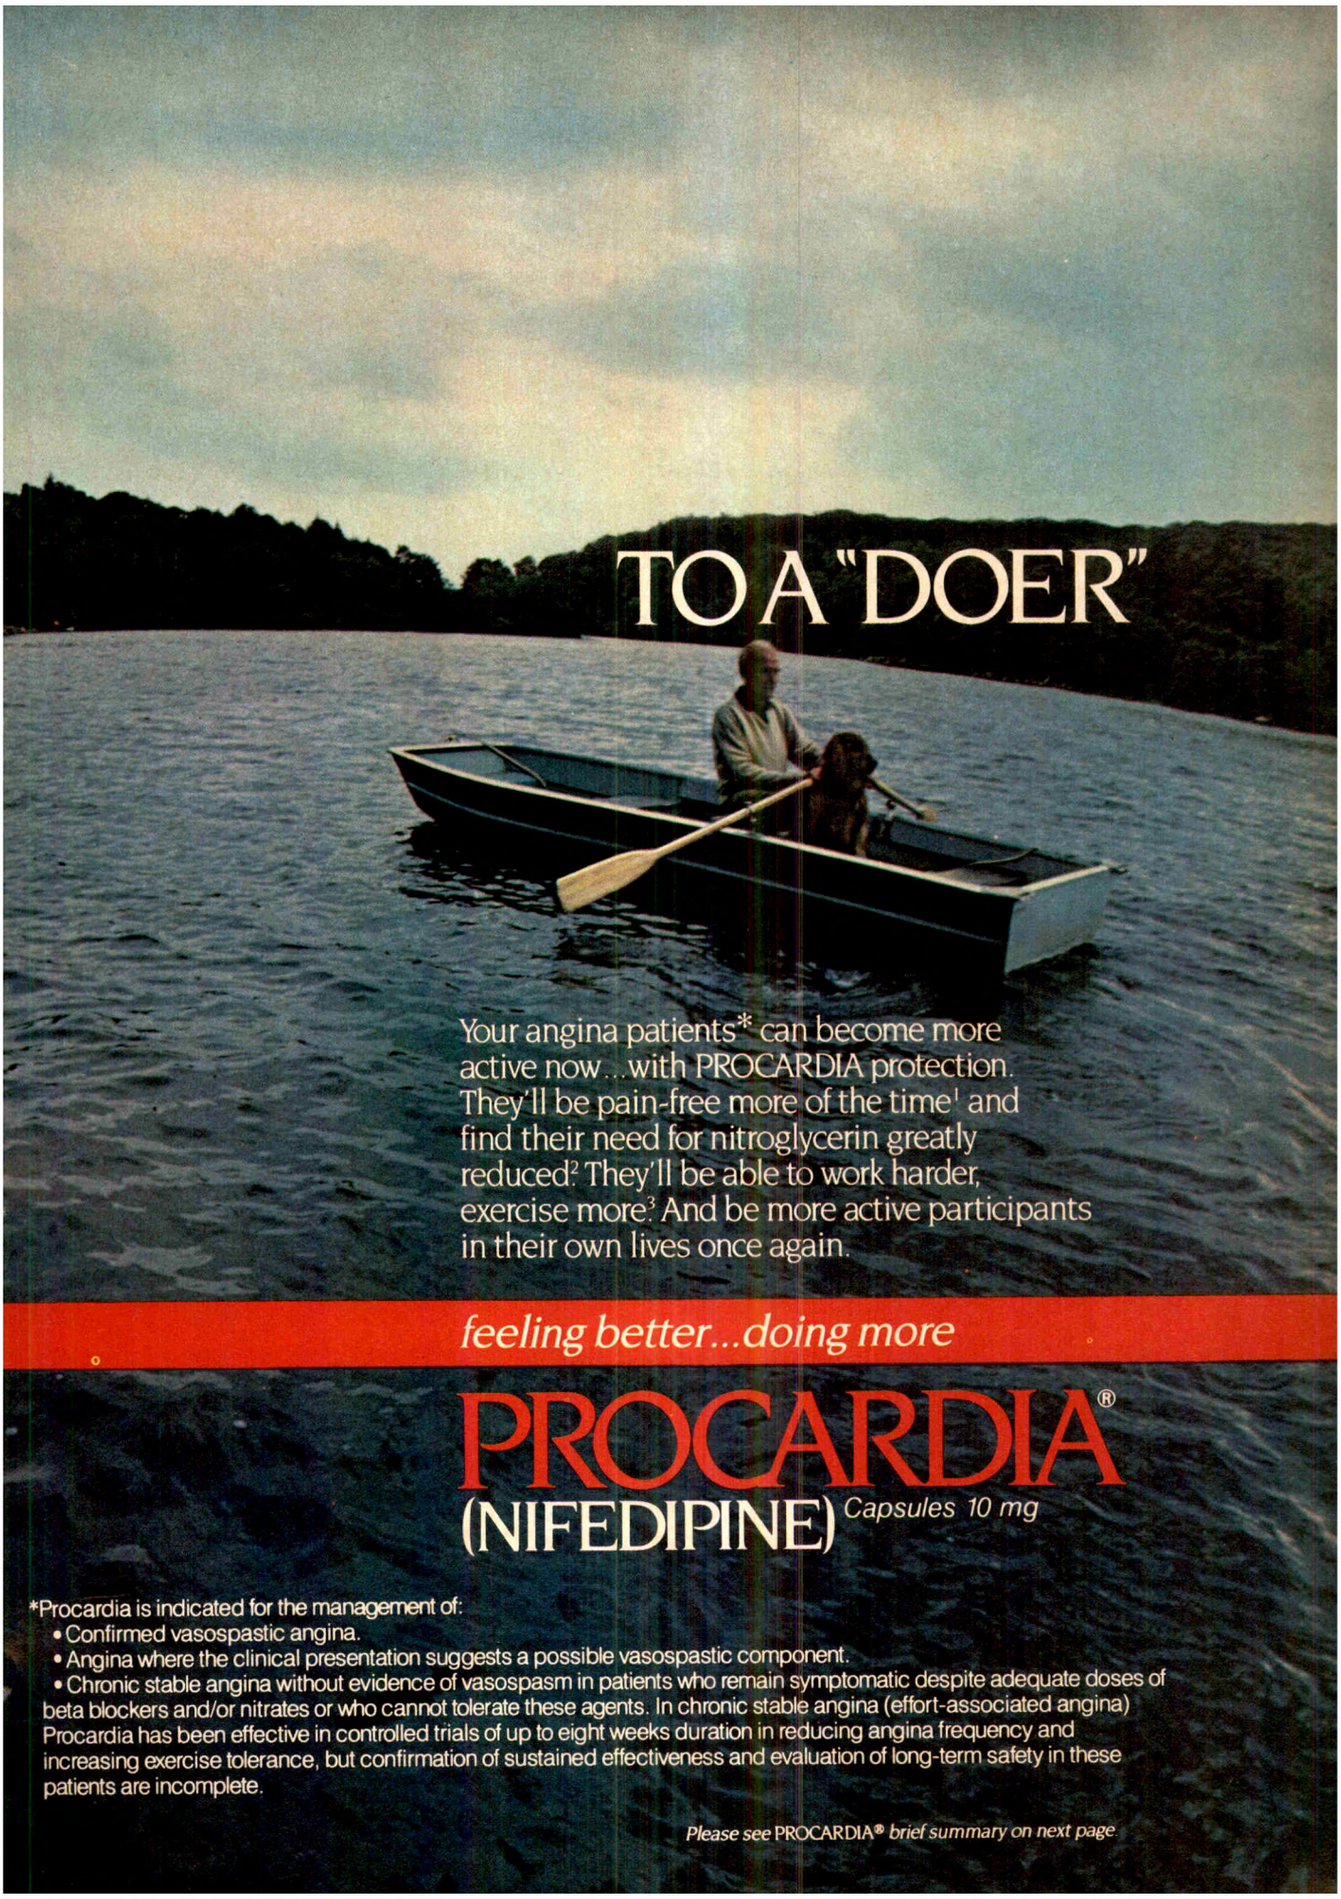
FROM A "WATCHER"...



*Procardia is indicated for the management of:

- Confirmed vasospastic angina.
- Angina where the clinical presentation suggests a possible vasospastic component.
- Chronic stable angina without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or nitrates or who cannot tolerate these agents. In chronic stable angina (effort-associated angina) Procardia has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Please see PROCARDIA® *brief summary on next page.*

feeling better...doing more

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

–Usual effective dosage is 30-60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because Procardia decreases peripheral vascular resistance, careful monitoring of blood pressure during initial administration and titration is suggested. Close observation is especially recommended for patients taking medication known to lower blood pressure.

–Offers a favorable safety profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

BRIEF SUMMARY
PROCARDIA® CAPSULES For Oral Use
(nifedipine)

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in those patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Carcinogenesis, mutagenesis, impairment of fertility: When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose.

Pregnancy: Category C. Please see full prescribing information with reference to teratogenicity in rats, embryotoxicity in rats, mice and rabbits, and abnormalities in monkeys.

ADVERSE REACTIONS: The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, diarrhea, constipation, inflammation, joint stiffness, shakiness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, and sexual difficulties. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

Laboratory Tests: Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms. Cholestasis, possibly due to PROCARDIA therapy, has been reported twice in the extensive world literature.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

CORONARY HEART DISEASE

Effects of Discontinuing Maintenance Digoxin Therapy In Patients With Ischemic Heart Disease and Congestive Heart Failure in Sinus Rhythm

MIHAI GHEORGHIADE, MD and GEORGE A. BELLER, MD

To evaluate the importance of oral maintenance digoxin therapy in chronic congestive heart failure (CHF), 24 patients in sinus rhythm on maintenance digoxin for documented CHF were studied prospectively on and off the drug. The average duration of therapy was 39 months (range 2 to 180). All 24 patients had documented coronary artery disease (CAD): 22 were in New York Heart Association functional class III and 2 in class II. Twenty-one patients (88%) were receiving diuretic or vasodilator therapy, or both, before digoxin discontinuance. At 1 month off digoxin and with no increase in doses of other medications excepting minor increases in antianginal therapy in 2 patients, no difference was observed in the group as a whole in symptoms, resting heart rate, arterial blood pressure, physical findings, weight, cardiothoracic ratio, radiographic signs of pulmonary congestion, radionuclide left ventricular ejection fraction (LVEF), duration of symptom-limited treadmill exercise (14 patients), or CHF score, compared with evaluation during maintenance digoxin therapy. Similar results were obtained in a subgroup of 9 patients with a resting LVEF <0.35 (0.27 ± 0.02; mean $\pm$ standard error of the mean). Six patients had a decrease and 5 patients an increase in LVEF of ≥ 0.05 units after cessation of digoxin. Off digoxin, the CHF score increased by only 1 point in 2 patients, but also decreased in 2 patients. Thus, in this study population comprised of patients with CAD with documented CHF, most of whom were receiving diuretics or vasodilators, or both, digoxin withdrawal had no adverse clinical or hemodynamic effects.

Although digitalis glycosides were introduced for treatment of cardiac maladies almost 200 years ago, controversy persists regarding the effectiveness and worth of the drug in the treatment of congestive heart failure (CHF). There is no doubt that cardiac glycosides are highly effective in controlling the ventricular response in the presence of atrial fibrillation. Previous work has shown that various digitalis preparations can improve cardiac performance when the drug is administered acutely under various conditions and indexes of myocardial contractility are measured.[1–3] Despite the demonstration of myocardial inotropic stimulation with short-term administration, controversy persists concerning the clinical and hemodynamic effects of chronic digitalis administration in patients with chronic coronary artery disease (CAD) in sinus rhythm with or without CHF.

From the Cardiology Divisions, Veterans Administration Hospital, Salem; and the University of Virginia Medical Center, Charlottesville, Virginia.
Manuscript received September 20, 1982; revised manuscript received January 6, 1983, accepted January 10, 1983.
Address for reprints: Mihai Gheorghiade, MD, Cardiology Section 11B, Veterans Administration Medical Center, Salem, Virginia 24153.

Given the fact that toxic manifestations of digitalis therapy comprise some of the most prevalent adverse drug reactions encountered in clinical practice,[4] it is disturbing that precise knowledge regarding which patients benefit from this drug and which do not is still lacking. The present study prospectively evaluates clinical and hemodynamic effects of digoxin discontinuance in patients with sinus rhythm with a clearly documented history of chronic CAD and CHF. We sought to evaluate not only alteration in symptoms after discontinuance of the drug but also changes in left ventricular function and exercise capacity. The major difference in study design from previous studies of digitalis withdrawal is that most patients in the present investigation were maintained on diuretic or vasodilator drugs, or both, during the period off digoxin. Also, the group was rather homogeneous in that all had CHF secondary to CAD.

Methods

Patient population: One hundred fourteen patients receiving maintenance digoxin were evaluated for possible inclusion into the study. Of these, 87 patients were excluded from participation in the trial for a variety of reasons including chronic atrial fibrillation in 26, no evidence of CHF or unclear indications for initial digitalization, or both, in 12, poorly documented history of CHF in 24, digitalization for CHF in the setting of acute myocardial infarction in 10, no CAD in 5, and subtherapeutic plasma digoxin levels in 10. The remaining 27 patients had CAD with documented previous myocardial infarction and all were studied prospectively. Of these, 2 patients were unable to complete the protocol. One patient, an 85-year-old man with a documented history of CAD, died suddenly 3 weeks after digoxin discontinuance. Before his death, no signs or symptoms consistent with worsening of CHF were evident. A second patient did not return for the 1 month follow-up visit but clinically his condition was stable off digoxin. A third patient had an unexpected plasma digoxin level of 0.9 mg/ml 1 month after allegedly discontinuing the drug. He subsequently admitted to resuming digoxin despite instructions to the contrary, and thus had to be eliminated from the study. Of the remaining 24 patients completing the protocol, all were men. Their mean age was 60 years (range 42 to 80). No patient had a history of atrial tachyarrhythmias.

The indication for initiating long-term digoxin therapy in all 24 patients was the presence of clinical or radiographic evidence of CHF, or both. At initial digitalization, 13 patients related symptoms of dyspnea on exertion, orthopnea, and paroxysmal nocturnal dyspnea, and exhibited signs of sinus tachycardia, jugular venous distention, pulmonary rales, and an S_3 gallop. They demonstrated radiographic evidence of CHF such as cardiomegaly, pulmonary venous hypertension, interstitial edema, alveolar edema, or pleural effusion. In the remaining 11 patients, digitalization was prompted by symptoms and/or signs and/or radiographic findings of CHF but not all 3 as in the other 17 patients.

Twenty-two patients were in New York Heart Association functional class III and the remaining patients in class II. In no instance was CHF precipitated solely by recurring episodes of acute ischemia. All patients had chronic CHF. The duration of maintenance digoxin therapy before discontinuation ranged between 2 and 180 months (average 39). Plasma digoxin levels were obtained 6 to 8 hours after the last digoxin dose and ranged from 0.8 to 2.2 ng/ml (1.2 ± 0.3 ng/ml, mean ± standard deviation). Figure 1 summarizes the serum digoxin data in the 24 patients who completed the protocol. All had therapeutic serum digoxin levels. Twenty-one patients (88%) were receiving diuretic or vasodilator therapy, or both, for CHF before digoxin withdrawal. This included furosemide therapy in 12 (mean daily dose 55 mg; range 20 to 80), hydrochlorothiazide in 8 patients (mean daily dose 50 mg; range 25 to 100), hydralazine therapy in 2 (mean daily dose 93 mg; range 40 to 200), oral isosorbide dinitrate therapy in 13 (mean daily dose 66.1 mg; range 40 to 120), and nitroglycerin ointment in 3 (4 inches daily). Dosages of diuretics and vasodilators for individual patients were derived from clinical assessment. Diuretic doses were increased to the level of dry weight status without excessive volume depletion. Vasodilator doses to maximal efficacy were guided by arterial blood pressure responses, and in the case of nitrates, avoidance of side effects such as headache and dizziness. A total of 20 patients (83%) were receiving diuretics and 16 (66%) vasodilators. Fourteen patients were receiving both diuretics and vasodilators and 2 patients were taking a long-acting nitrate preparation and another vasodilator.

Concurrent therapy for CHF or angina pectoris was not altered during the follow-up period except in 2 patients in whom the isosorbide dinitrate therapy was initiated because of symptoms consistent with worsening of angina pectoris. In these patients no worsening of CHF was observed before beginning nitrate therapy.

Informed consent was obtained for each patient for digitalis withdrawal after detailed explanation of the study protocol. While patients were still receiving maintenance digoxin therapy and before drug discontinuance, baseline studies were obtained and consisted of the following: a complete cardiovascular history, physical examination including measurement of body weight, a resting 12-lead electrocardiogram, a standard posteroanterior chest roentgenogram, a resting gated cardiac blood pool scan, and a symptom-limited treadmill exercise test. Serial exercise testing as a method of assessment was introduced midway into the study, and hence, only 14 consecutive patients were studied in this manner. Each patient was assigned a heart failure score which is based on symptoms, signs, and findings on chest roentgenography. For this scoring system, each of the following signs or symptoms was assigned 1 point: dyspnea on exertion, paroxysmal nocturnal dyspnea, sinus tachycardia, jugular venous distention, pulmonary end-inspiratory rales, an S_3 gallop, a cardiothoracic ratio >0.5, radiographic interstitial edema, alveolar changes, pulmonary venous hypertension, pleural effusion, and peripheral edema. Thus, the score assigned ranged from zero, which reflected an absence of the 12 variables listed above, to a maximal score

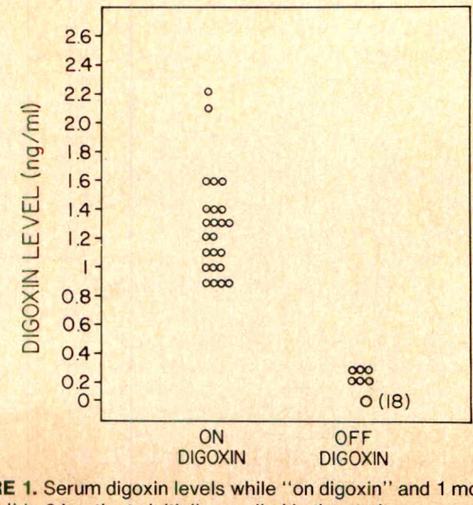

FIGURE 1. Serum digoxin levels while "on digoxin" and 1 month "off digoxin" in 24 patients initially enrolled in the study.

TABLE I Heart Rate (HR), Blood Pressure, Body Weight, and Exercise Tolerance Before and After Digoxin Discontinuance

	On Digoxin	Off Digoxin
HR (beats/min)	75 ± 2	73 ± 2
Blood pressure (systolic/diastolic)	122 ± 4/73 ± 2	125 ± 3/72 ± 2
Body weight (kg)	78.3 ± 2.7	78.2 ± 2.7
Exercise capacity (min)*	7.1 ± 1.2	7.8 ± 0.9

* Exercise testing conduction in 16 consecutive patients.

of 12, representing the presence of each of the listed findings.

Serum digoxin determination: The serum digoxin was measured by a standard commercial radioimmunoassay technique employing iodine-125-digoxin as the standard (Abbott Laboratories).

Chest roentgenography: In all instances, the cardiothoracic ratio was measured and the lung fields were evaluated for signs of pulmonary congestion by 2 radiologists interpreting the X-ray independently without knowledge of the patient's clinical status. Differences in interpretation were resolved by a third observer and the majority opinion prevailed.

Exercise test protocol: Maximal symptom-limited, graded exercise treadmill testing was conducted according to a modified Bruce[5] or National Institutes of Health protocol. In the modified Bruce protocol, exercise testing was initiated at 1 mph and 5% grade. Both speed and incline were increased every 3 minutes to 1.4 mph and 7% grade, 1.7 mph and 10% grade, 2.5 mph and 12% grade, 3.4 mph and 14% grade, 4.2 mph and 16% grade, and 5.0 mph and 18% grade. Employing the National Institutes of Health protocol, the treadmill was started at 2.2 mph and 0% grade. The speed was then held constant but the grade increased 2.5% every 2.5 minutes. The test was performed with the patient in the postabortive state. Because of the potential "training effect," each patient had 2 treadmill tests while on maintenance digoxin, and only the result from the second test was used for comparison with the exercise test after digoxin was withdrawn.

Radionuclide techniques: In vivo red blood cell labeling was accomplished by intravenous injection of 7.5 mg stannous pyrophosphate followed 20 minutes later by 25 mCi technetium-99m pertechnetate. A gamma camera (Ohio Nuclear Sigma 410; VIP 450 computer with dual floppy discs) was positioned over the patient's chest in a 50° left anterior oblique position. This maximized separation of the right and left ventricles. A computer program (Multi-Interval Cardiac Analysis Package) was used for both background subtraction and smoothing and edge detection and for setting the designated area of interest. Left ventricular ejection fraction was calculated by subtracting end-systolic counts from end-diastolic counts and dividing by the end-diastolic counts minus background counts. All radionuclide angiographic data was calculated without knowledge of the patient's clinical status or knowledge of the other quantitative measurements.

Follow-up studies: After completion of the baseline evaluation, the administration of digoxin was discontinued in all patients. All patients who had a baseline ejection fraction of <0.35 had the drug withdrawn while under observation in the hospital for a period of 10 days. These patients were evaluated on a daily basis for any clinical signs or symptoms consistent with cardiac decompensation. Each patient in the entire group was reexamined at 2 and 4 weeks after digoxin withdrawal, and monthly thereafter for an average of 4 months (range 2 to 8). At the 2-week visit, a complete cardiac history, physical examination, chest roentgenogram, and 12-lead electrocardiogram were again obtained. At the 1-month visit a chest roentgenogram and a 12-lead electrocardiogram only were repeated and another symptom-limited exercise test, a resting radionuclide ejection fraction, and plasma digoxin level were obtained. At each month thereafter, follow-up involved solely clinical and radiographic parameters.

Statistical analysis: Values are expressed as mean ± standard error of the mean. Comparison between baseline and digoxin withdrawal studies in individual patients were made using the paired t test, and comparison between groups was performed using analysis of variance.

Results

One month after digoxin withdrawal, no significant difference was observed in cardiac symptoms, resting heart rate, systolic, diastolic, or mean blood pressure, body weight, physical findings, cardiothoracic ratio, radiographic signs of pulmonary congestion, radionuclide ejection fraction, duration of symptom-limited treadmill exercise, or the heart failure score compared with the baseline evaluation gathered during chronic maintenance digoxin therapy.

Heart rate: As shown in Table I, the mean heart rate at rest was 75 ± 2 beats/min during digoxin therapy and 76 ± 2 beats/min after digoxin discontinuance, respectively. This difference was not statistically significant (NS).

Blood pressure: Digoxin withdrawal had no significant influence on mean systolic or diastolic blood pressure. Systolic and diastolic blood pressure was 122 ± 4 mm Hg and 73 ± 2 mm Hg, respectively, during maintenance digoxin and increased insignificantly to 125 ± 3 mg Hg and 72 ± 2 mm Hg at 1 month after digoxin discontinuance (Table I).

Body weight: As shown in Table I, mean weight was 78.3 ± 2.7 kg on digoxin and 78.2 ± 2.7 kg off digoxin (NS).

Cardiothoracic ratio: The cardiothoracic ratios in this group of patients before and after digoxin discon-

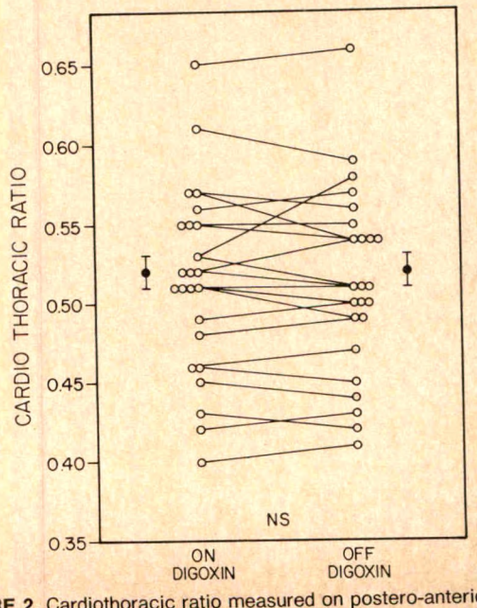

FIGURE 2. Cardiothoracic ratio measured on postero-anterior chest roentgenogram on and 1 month off digoxin. NS = not significant.

tinuance are shown in Figure 2. Most patients (67%) had cardiomegaly as defined by a cardiothoracic ratio >0.5. At 1 month of digoxin discontinuance, the cardiothoracic ratio was unchanged compared with the baseline measurements (0.53 ± 0.01 and 0.53 ± 0.01, respectively).

Left ventricular ejection fraction: Figure 3 summarizes left ventricular ejection fraction (LVEF) data in this group of patients. Both individual and mean values on and off digoxin are shown. The mean LVEF was 0.41 ± 0.03 during chronic maintenance digoxin therapy and was 0.41 ± 0.03 at 1 month of digoxin discontinuance. After digoxin withdrawal, no change in LVEF was observed in 15 patients, defined as an increase or decrease of ≥0.05 units. Six patients had a decrease and 3 patients showed an increase in LVEF of ≥0.05 units. The mean baseline LVEF before digoxin withdrawal in the 6 patients demonstrating a decrease in LVEF off digoxin was 0.45 ± 0.06, compared with 0.40 ± 0.03 in the remaining 18 patients who showed no change (n = 15) or an increase (n = 3) in ejection fraction after 1 month of digoxin discontinuance (NS). Thus, baseline LVEF was not significantly different in the 2 groups.

The heart failure score was 2.42 ± 0.50 on digoxin in the 6 patients who subsequently showed a decrease in LVEF, compared with 2.15 ± 0.30 in the 22 patients in whom LVEF increased or remained unaltered off digoxin (difference also was NS). Only 1 of the 6 patients demonstrating a decrease in LVEF off digoxin had a concomitant increase in heart failure score (by 1 point). A decrease in LVEF off digoxin did not correlate with a worsening of heart failure score. The mean cardiothoracic ratio in the 6 patients showing a decrease in LVEF off digoxin (0.50 ± 0.01) was not significantly greater than that in patients showing no change or a decrease in LVEF after drug discontinuance (0.52 ± 0.01). Thus, these 2 subgroups were comparable with respect to baseline heart size as judged by chest roentgenographic measurements.

Figure 4 shows that even when a subgroup of 9 patients with marked left ventricular dysfunction are analyzed separately (ejection fraction ≤0.35), no significant change was noted off digoxin (0.27 ± 0.02 versus 0.28 ± 0.02). Of these 9 patients, only 1 had a decrease >0.05 units in ejection fraction when digoxin was discontinued.

Exercise capacity: Serial treadmill exercise testing was conducted in 14 patients (Table I). There was no significant change in the duration of treadmill time between baseline and digoxin withdrawal states, 6.1 ± 0.8 and 7.2 ± 0.9 minutes, respectively. Off digoxin, the duration of symptom-limited treadmill time was increased in 6 patients, decreased in 1, and unchanged in the remaining 7. Baseline characteristics in the 14 patients undergoing treadmill testing were not significantly different from those in the remaining 10 patients.

Heart failure score: As shown in Figure 5, there was no significant difference in the derived mean heart failure score when baseline and digoxin withdrawal values were compared. The score was 2.1 ± 0.3 on digoxin and 2.1 ± 0.3 off digoxin (NS). The fact that the scores were relatively low to begin with reflected the compensated state these patients were in before withdrawal of the glycoside. Off digoxin, the heart failure score was unchanged in 20 patients and increased by 1 point in 2 patients. The heart failure score decreased by 1 point in 2 patients. The 2 patients who showed an increase in heart failure score off digoxin had an S_3 gallop while on digoxin, as compared with 3 of 25 patients with an unchanged or improved heart failure score. Decompensation in 1 of the 2 patients showing an increase in heart failure score can probably be attributed to discontinuance of maintenance diuretic or vasodilator drugs, or both, during the period off digoxin (Fig. 6). The second patient had resting sinus tachycardia 1

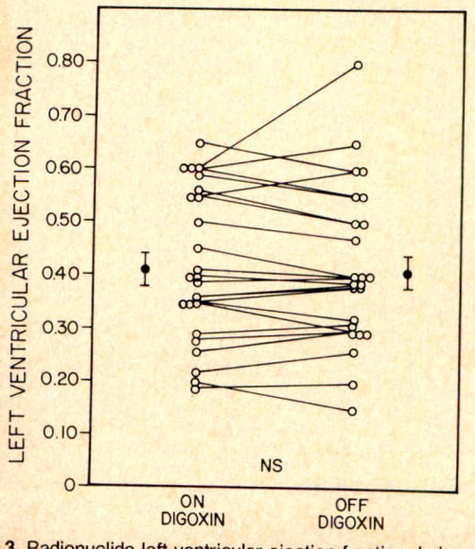

FIGURE 3. Radionuclide left ventricular ejection fraction during chronic maintenance digoxin therapy and at 1 month of digoxin discontinuance. NS = not significant.

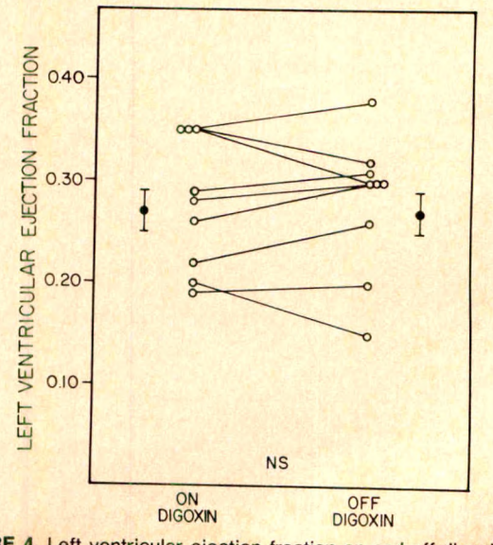

FIGURE 4. Left ventricular ejection fraction on and off digoxin in a subgroup of 9 patients with ejection fractions ≤0.35.

month off digoxin, but no other clinical or radiographic signs of CHF. The 1 point increase in heart failure score off digoxin in this patient was secondary to the increase in the sinus rate.

Discussion

The results of this study show that cessation of oral maintenance digoxin therapy in a group of 24 male patients in sinus rhythm with documented ischemic heart disease and compensated CHF had little adverse effects. Only 2 of the 24 patients demonstrated an increase in heart failure score after digoxin withdrawal. With digoxin discontinuance in the 24 patients, there was no gain in mean body weight, increase in heart size by radiographic criteria, or appearance of radiographic pulmonary vascular congestion. Exercise tolerance did not decrease in those patients undergoing serial testing. Likewise, in the group as a whole, no deterioration in resting LVEF was apparent off digoxin. Even when a subgroup of 9 patients with severely compromised left ventricular systolic dysfunction (mean LVEF 0.27) was analyzed separately, no worsening of clinical status or exercise tolerance or further decrease in ejection fraction could be detected. It must be emphasized that all these patients had chronic ischemic heart disease and most (88%) were receiving diuretic or vasodilator therapy or both concurrent with digoxin discontinuance. One potential hazard of discontinuing digoxin in patients with chronic heart failure is the emergence of supraventricular tachyarrhythmias. In this study, no such arrhythmias developed.

The indications for the initial digitalization were well documented in this study population. A potential criticism of this or similar studies is that digitalis therapy may not have been warranted in the first place. Interestingly, 36 of the 114 patients initially screened for the withdrawal protocol were receiving maintenance digoxin without any documentation of CHF or other accepted indications for digitalization. These patients would obviously have done well after digoxin discontinuance because they did not require the drug in the first place. None was included in the study group. In the present study, all patients had documented CHF by objective criteria. Patients were judged to be compensated at the time of digoxin withdrawal, explaining a rather low baseline heart failure score. On initial digitalization during decompensated CHF, the mean score for the group would have been higher.

For more than 100 years after the first description of the use of digitalis in the management of patients with edema by Withering[6] in 1758, the concept was held that digitalis was to be employed in the treatment of edema, particularly in the presence of atrial fibrillation. The teachings of McKenzie and Lewis in the early 1900s reinforced the recommendation that digitalis be used predominantly in atrial fibrillation. Not until the 1920s, based on the work of Christian,[7,8] Luten,[9] and Marvin,[10] was this view opposed and evidence presented that the drug was equally effective in CHF and sinus rhythm as in atrial fibrillation. The controversy persisted, and in 1939 Gavey and Parkinson[11] reported that digitalis produced similar but modest responses in nonrheumatic

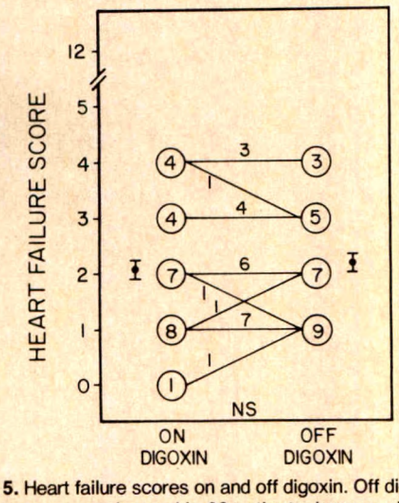

FIGURE 5. Heart failure scores on and off digoxin. Off digoxin, the heart failure score was unchanged in 20 patients, increased by 1 point in 2 patients, and decreased by 1 point in 2 patients. NS = not significant. Number of patients designated inside **circles**.

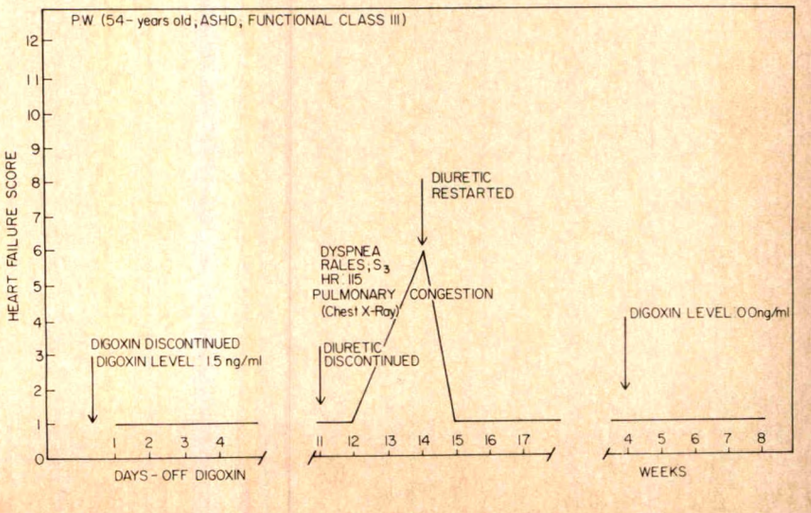

FIGURE 6. This patient did well for 11 days off digoxin, at which time the diuretic drug was withdrawn. Three days later, the patient presented with symptoms and signs of heart failure. When only the diuretic was restarted, the patient returned to the baseline compensated state. Digoxin was not reintroduced at any time. ASHD = arteriosclerotic heart disease; HR = heart rate.

patients whether they were in atrial fibrillation or in sinus rhythm. In their report, 16 patients in sinus rhythm who did not respond to digitalis did have a diuresis after the administration of a mercurial diuretic. The belief that digitalis was a highly effective drug in the treatment of CHF and sinus rhythm was reinforced by the emergence of hemodynamic studies in the 1940s.[12,13] Rader et al [14] concluded that most symptoms of CHF were a reflection of circulatory congestion and did not bear any relation to cardiac function. Removal of the congestive state with either digitalis or diuretics was associated with marked clinical improvement, whether or not the drugs altered intracardiac pressure or cardiac output. Although these studies demonstrated that inotropic cardiac stimulation was not required for relief of symptoms in most cases of CHF, the practice of cardiology changed little and digitalis remained the primary drug of choice for most patients with CHF.

Only recently have studies been undertaken to examine critically the efficacy of chronic maintenance digitalis therapy in the treatment of CHF.[15–25] With the advent of more potent diuretics and the demonstrated benefit of vasodilators in left ventricular unloading, the relative worth of digitalis in this multidrug approach is being reexamined. Starr and Luchi[15] withdrew digitoxin from elderly women who were in sinus rhythm. The results were entirely negative because neither patients nor investigators could distinguish between digitoxin treatment and control periods. Johnston and McDevitt[17] demonstrated that digitalis discontinuance in patients with normal sinus rhythm resulted in a 14% incidence of adverse effects. In their study, no objective hemodynamic or exercise parameters were evaluated and indications for the initial digitalization in the patient cohort were not described. Dall[18] and Krakauer and Petersen[21] showed that digoxin therapy could safely be discontinued in three fourths of elderly patients receiving the drug. Hull and Mackintosh[19] also reported that withdrawal of digoxin in patients with sinus rhythm did not produce any alterations in cardiovascular signs or symptoms. In these latter studies, there was also incomplete characterization of patients and lack of documentation of CHF. No serial hemodynamic or exercise data were presented.

In the study by McHaffie et al,[20] patients were first placed on oral furosemide, and after dry weight was achieved and edema resolved, exercise testing was performed to determine the benefit of oral digoxin added to the diuretic treatment. No evidence of symptomatic improvement or enhanced exercise tolerance could be detected when digitalis was added to the diuretic. No change in the cardiothoracic ratio was evident. Our results in a larger group of patients was comparable.

Other investigators have reached somewhat different conclusions. Fonrose et al[22] stopped digitalis therapy in a group of patients on a digitalis preparation for at least 1 year, with 50% requiring digoxin to be prescribed again within 3 to 21 days. The remaining 50% of the group were successfully maintained without the glycoside for periods of 4 months. In a placebo-control study reported by Dobbs et al[23] conducted in outpatients in whom a placebo was substituted for digoxin, 35% had a deterioration in their condition when digoxin was withdrawn. However, 28% had underlying atrial fibrillation. Of the patients whose condition deteriorated, 50% demonstrated improvement when digoxin was reintroduced. A pitfall of this study is that most data were obtained from questionnaires directed at eliciting changes in symptoms. Only a few patients demonstrated radiographic pulmonary congestion after withdrawal of digitalis. It is not clear which patients' condition deteriorated, those with sinus rhythm or those in atrial fibrillation, and the number of patients with atrial fibrillation in the group that had a relapse on placebo was not stated. The relation between deterioration and the type of underlying heart disease was not determined. Hence, no definitive conclusion regarding efficacy of digoxin therapy solely in patients with compensated CHF and sinus rhythm could be drawn. A common feature of the studies of Fonrose et al[22] and Dobbs et al[23] was that deterioration associated with digoxin withdrawal was manifested by increased salt and water retention. Decompensation might not have occurred if appropriate diuretic or vasodilator therapy, or both, had been maximized before digitalis discontinuance.

More recently, Arnold et al[24] studied only 9 patients during rest and after exercise on long-term digoxin therapy, after withdrawal of the drug, and 6 hours after readministration. All were in sinus rhythm. In this study, cessation of digoxin was associated with documented deterioration in left ventricular performance as indicated by a 13% decrease in mean cardiac index, a 24% decrease in stroke work index, and a 38% increase in pulmonary capillary wedge pressure. Worsening exercise hemodynamics were observed as well. With readministration of the drug, improvement was noted. A decrease in ejection fraction was noted in 7 of these 9 patients. This study included a rather small number of patients, and the variability of the hemodynamic changes in individual patients was significant. In fact, 4 of the 9 patients studied did not have a change in functional class after digoxin withdrawal. A major difference between Arnold's study and ours is that in the former only 3 patients had ischemic heart disease and only 3 patients were receiving vasodilators at the time of digitalis withdrawal. In the present study, all patients had ischemic heart disease with compensated CHF and were receiving diuretics or vasodilators, or both. Thus, differences in patient population could, in part, explain the difference in findings between Arnold's study and ours.

Lee et al,[25] in a controlled study, reported a benefit of oral digoxin compared with placebo in 56% of patients with chronic heart failure who were in sinus rhythm. Although most patients were receiving diuretics, only 24% were on vasodilators during placebo and digoxin study periods. In our study, 66% were receiving vasodilators at the time of digoxin withdrawal. This difference may perhaps account in part for the less beneficial effects of digoxin observed in our study. Also, all our patients had CHF secondary to ischemic heart disease

which was not the case in the group studied by Lee et al.[25] We confirm the observation of Lee et al of no change in LVEF when digoxin is discontinued.

Recently, Moss et al[26] and Bigger et al[27] suggested that chronic digitalis therapy after recovery from myocardial infarction may be an independent variable associated with increased mortality in patients with CHF, even when adjusted for relevant nondigitalis risk factor variables. The conclusions of these studies were that digitalis may increase the early postdischarge mortality of certain survivors of myocardial infarction. Our study population was comprised of patients with chronic ischemic heart disease. If digoxin has little salutary effect compared with diuretic and vasodilator therapy in these patients, caution should be exercised in choosing to put such patients on sustained maintenance therapy if an increased risk of sudden death exists, as suggested by these 2 reports.

From a review of the literature no definitive conclusion can be drawn concerning the efficacy of chronic digitalis therapy in patients with chronic ischemic heart disease.[28–38] In most instances, only a few patients were studied and many did not have CHF. Many studies investigated only the acute effects of intravenous digitalis. The hemodynamic improvement documented in these previous studies in patients with ischemic heart disease was slight to modest and can, for the most part, be attributed to enhanced contractility induced by the drug in normal segments. Comparison with vasodilators with regard to relative worth was not carried out. Raabe[39] showed that in acute myocardial infarction, intravenous digoxin showed no further hemodynamic benefit if nitroprusside was given first. Firth et al[40] studied 14 patients with coronary artery disease and compensated CHF. All were receiving nitrates or diuretics, or both, before digoxin administration. They found no significant effect of digoxin on ejection fraction at rest or at peak exercise. There was no effect on stroke volume or cardiac index, and digoxin did not prevent the exercise-induced increase in end-diastolic and end-systolic volume indexes in patients with an ejection fraction <0.5. No significant change in exercise tolerance was noted during digoxin therapy. Perhaps the lack of impressive improvement with digoxin in this series of patients is related to the fact that most were receiving vasodilators.

A limitation of our study is that assessments were made without "blinding" the investigators or patients to the "on" and "off" digoxin periods. Although this study was not double-blinded or randomized, we believe the major findings are valid. Certain objective endpoints such as cardiothoracic ratio and radionuclide ejection fraction were interpreted blindly by the physicians without knowledge of which study was obtained on or off digoxin. Also, no increase in mean body weight was observed which might have indicated fluid retention. Another limitation might be the somewhat brief duration of follow-up off digoxin after which the second set of measurements was made. Nevertheless, after an average of 4 months of follow-up off digoxin, no evidence of clinical decompensation was observed.

In conclusion, we found that in most patients in sinus rhythm and documented CHF secondary to ischemic heart disease, digoxin can safely be discontinued when diuretic and vasodilator therapies are maximized. Only 2 of 24 patients in the present study showed an increase in heart failure score when digoxin was discontinued. In one of these patients, no clinical deterioration was observed >1 week after digoxin withdrawal. When diuretic therapy was also discontinued by the patient, signs of overt CHF promptly developed. No significant changes in left ventricular ejection fraction and cardiothoracic ratio at 1 month of digoxin discontinuance in the group as a whole were seen. The effects of digoxin withdrawal on regional wall motion were not assessed in the study. Although the global LVEF was unchanged after digoxin discontinuance, regional wall motion might have been altered. Similarly, despite no observed change in mean ejection fraction after digoxin discontinuance, certain patients may have experienced a decrease in cardiac output. The latter hemodynamic parameter was not obtained in this study. It must be emphasized again that in contrast to the majority of previous studies addressing the issues of efficacy of chronic digitalis therapy, all patients in the present study were digitalized initially for documented symptoms and signs of CHF. These data suggest that a randomized, double-blind study could safely be undertaken to assess the clinical use of digoxin therapy for heart failure in patients in sinus rhythm concurrently receiving diuretic or vasodilator drugs or both.

Acknowledgment: We gratefully acknowledge Christine L. Tulley, MD, and Clifford P. Culpepper, MD, for clinical assistance; Peter P. Sforza, Otoneil R. Sullesta, and E. Gifford Ammermann, who provided the blinded radiographic interpretations and radionuclide measurements in the study patients; and Nancy Durham for superb secretarial assistance.

Efficacy and Safety of Verapamil in Patients With Angina Pectoris After 1 Year of Continuous, High-Dose Therapy

DONALD A. WEINER, MD, CAROLYN H. McCABE, BS, SALLY S. CUTLER, BS, MARK A. CREAGER, MD, THOMAS J. RYAN, MD, and MICHAEL D. KLEIN, MD

The long-term efficacy and safety of high-dose verapamil therapy (480 mg/day) was assessed in 26 patients with chronic stable angina pectoris during a 3-phase protocol: Phase 1—an initial, 6-week placebo-controlled, double-blind crossover assessment; Phase 2—an open label, 1-year follow-up; and Phase 3—a final drug withdrawal and rechallenge 10-week study. Three patients withdrew during Phase 2 (1 had hepatitis and 2 underwent coronary bypass surgery). Adverse effects during Phase 2 were mild, consisting of constipation (6 patients) and prolongation of the P-R interval (5 patients); however, no patient required alteration of the 480 mg/day dosage. At the end of Phase 2, 10 patients underwent the Phase 3 study, commencing with a 2-week period in which verapamil was either tapered gradually or abruptly discontinued. This was followed by an 8-week double-blind, placebo-controlled crossover rechallenge study with verapamil.

The clinical and exercise responses to verapamil compared with placebo were similar during the Phase 3 protocol and the initial Phase 1 study (treadmill time increased by 55% and anginal attacks per week decreased by 63% during Phase 3, compared with a 28% increase and a 42% decrease, respectively, during Phase 1, p = not significant [NS]). Withdrawal of verapamil produced a similar return of anginal symptoms whether the drug was abruptly discontinued or its administration tapered. No patient had unstable angina pectoris or acute myocardial infarction.

These investigations demonstrate that verapamil is safe and effective when evaluated after 1 year of continuous therapy using a dosage of 480 mg/day. There is no evidence of drug tachyphylaxis, nor does verapamil appear to cause an abrupt withdrawal syndrome in patients with chronic stable angina pectoris.

The development of calcium-channel blocking agents represents a tremendous advance in the treatment of ischemic heart disease. Verapamil belongs to this class of drugs, and its beneficial effects in the treatment of patients with exertional angina pectoris are well documented in several short-term controlled studies.[1–7] Its long-term efficacy and safety, however, have not been well demonstrated using a carefully designed trial.

We have previously reported that patients with stable exertional angina pectoris had a beneficial response to verapamil in a short-term controlled study.[8] The present investigation extends those initial observations to determine the efficacy and safety of high-dose verapamil therapy after 1 year of continuous therapy. Patients were then withdrawn from verapamil and rechallenged in a controlled trial for the following objectives: (1) to determine whether tachyphylaxis to the drug occurred after 1 year of therapy, and (2) to evaluate whether a withdrawal syndrome occurs upon abrupt cessation of verapamil therapy.

Methods

Study population: Twenty-six male patients with a mean age of 55 years (range 30 to 72) were enrolled in the protocol. All patients were diagnosed as having chronic stable angina pectoris of at least 6 months in duration, having at least 5 episodes per week in addition to an abnormal treadmill exercise test, consisting of both ischemic (≥1 mm) S-T segment depression and exercise-induced angina. No patient had a history of congestive heart failure, systemic hypertension (>150/100 mm Hg), sinus bradycardia (<50 beats/min), atrioventricular block, renal or hepatic dysfunction, or myocardial infarction within the previous 3 months, although 10 patients had a history of myocardial infarction. Sixteen patients were classified as New York Heart Association func-

tional class 2 and 10 patients as functional class 3. Seventeen patients underwent coronary angiography: 4 had 1-vessel coronary disease, 6 had 2-vessel disease, and 7 had 3-vessel disease. Ninety-two percent of the catheterized patients had a left ventricular ejection fraction >50%. No patient had evidence of congestive heart failure on examination.

Study protocol (Fig. 1): The patients initially underwent a dose-seeking, single-blinded period. All patients tolerated verapamil in a dose of 480 mg/day without severe adverse effects. They then were enrolled in a protocol consisting of 3 separate phases. Phase 1 consisted of an initial 6-week, randomized, double-blind crossover study. The details of this phase have been reported elsewhere.[8] In brief, each patient received either placebo or verapamil, 480 mg/day, for 2-week periods, followed by a 1-week, drug tapering period. Phase 2 comprised a 1-year, open-label drug trial in which all patients received 480 mg/day of verapamil. No additional antianginal medication was administered during this phase except for sublingual nitroglycerin. Phase 3 consisted of a 10-week, randomized, placebo-controlled, double-blind crossover study after the patients were first withdrawn from verapamil. During the first 2 weeks of this phase, verapamil was discontinued either abruptly or tapered gradually over 4 days in a random fashion. The patients then entered an 8-week, randomized, double-blind crossover phase during which verapamil, 120 mg 4 times per day, or identical appearing placebo was administered for 2 weeks. At the end of the 2 weeks during which verapamil had been given (either crossover A or B), the drug was withdrawn either abruptly or tapered over 4 days, opposite to the method used during the initial 2 weeks. Thus, all the patients underwent both an abrupt withdrawal and a tapering (over 4 days) withdrawal from verapamil therapy. During Phase 3, as was done during Phase 1, the patients were permitted to use sublingual nitroglycerin as needed to treat anginal episodes, but no additional cardioactive medications were administered other than the test capsules, which were given 4 times daily.

The patients were evaluated weekly during Phase 1, every 3 months during Phase 2, and weekly during Phase 3 by the same research assistant and physician. Each patient signed an informed consent form approved by the Institutional Review Board at Boston University Medical Center at the beginning of each of the 3 phases of the protocol. If the patients did not wish to participate in Phase 3, they were continued indefinitely in the open-label trial.

Exercise tests: Treadmill exercise tests using the Bruce protocol[9] were performed 5 times during Phase 1, once at the end of Phase 2, and 5 times during Phase 3 (Fig. 1). A 12-lead electrocardiogram and blood pressure were recorded at rest and at 1-minute intervals during exercise and recovery, until the heart rate, blood pressure, and S-T segments returned to baseline. All patients were exercised maximally to a symptom-limited endpoint each time. Parameters analyzed on the exercise test included total exercise duration on the treadmill; time to the onset of 1 mm of horizontal or downsloping S-T segment depression; peak S-T segment depression; P-R interval at rest; and heart rate, systolic blood pressure, and rate-pressure product (heart rate × systolic blood pressure) at rest, during submaximal exercise (defined as the end of stage 1 of exercise), and maximal exercise.

Blood verapamil levels: Verapamil blood levels were sampled in each patient at the end of crossover A and B during Phase 1 and at the end of each 2-week period during Phase 3 (Fig. 1). Samples were drawn 2 hours after the last capsule had been ingested. Serum drug concentrations were measured at the Bioscience Laboratories, Chicago, Illinois, utilizing the high-pressure liquid chromatographic method of Harapat and Kates.[10] Verapamil blood levels were used to measure patient compliance in taking medication and to assess the completeness of drug washout.

Statistics: A 2-way analysis of variance for repeated measures was used to determine if significant differences occurred between the group mean values. If the analysis of variance indicated a significant difference in the mean values for a parameter, a 2-tailed, paired Student's t test was applied. Probabilities were considered significant at the 0.05 level. All values are expressed as mean ±1 standard deviation.

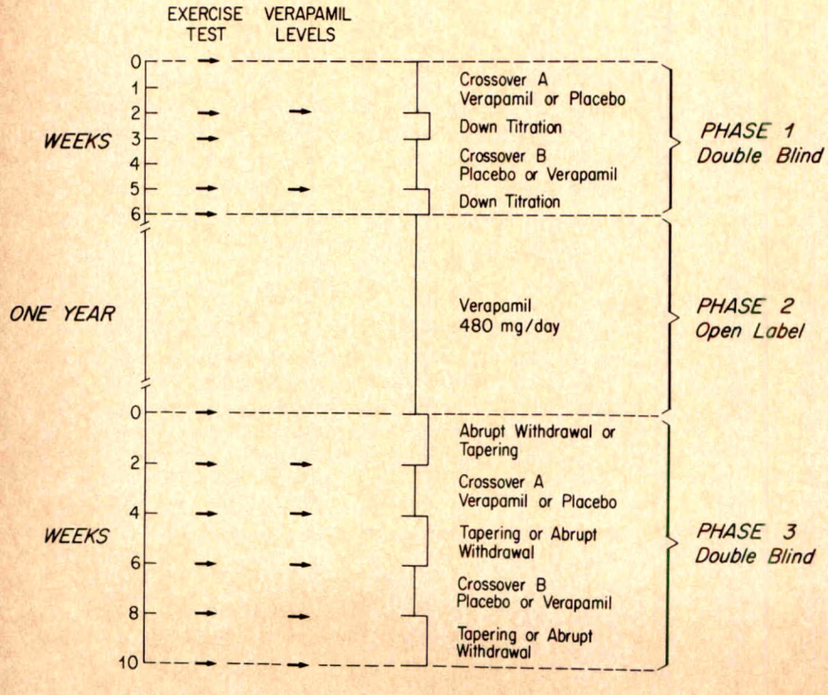

FIGURE 1. Protocol design. The entire protocol consisted of 3 phases: Phase 1, an initial 6-week, double-blind, crossover study; Phase 2, a 1-year, open-label, drug efficacy and safety trial; and Phase 3, a 10-week, double-blind, crossover drug withdrawal and rechallenge study.

TABLE I Acute and Long-Term Effects of Verapamil in 23 Patients

Variable	Phase 1: Placebo	Verapamil Therapy	
		Phase 1	Phase 2
Anginal episodes per week	6.3 ± 7.5	2.5 ± 4.1†	2.8 ± 5.1*
Nitroglycerin tablets per week	7.6 ± 10.2	2.7 ± 5.2*	3.0 ± 9.3*

Results

Dropouts and drug safety: Twenty-six patients were entered into the protocol, and all completed Phase 1. One patient had abnormal liver function test results in Phase 1 at the end of crossover B while taking verapamil and was withdrawn from Phase 2. Two other patients dropped out during Phase 2 because of elective coronary bypass surgery at 5 and 10 months.

No patient required readjustment of the high-dose verapamil (480 mg/day) because of adverse effects during Phase 2. Minor adverse effects consisted of constipation in 6 patients (22%) approximately 1 week after starting verapamil, with 3 requiring treatment with stool softeners. Electrocardiographic changes were observed in 6 patients; five patients had prolongation of the P-R interval by 20 to 40 ms, but did not have first degree heart block, and 1 patient had intermittent, asymptomatic junctional rhythm at rest.

At the end of Phase 2, the remaining 23 patients were approached to undergo a 10-week drug withdrawal and rechallenge study (Phase 3) after they had been taking verapamil continuously for 1 year. Ten of the 23 patients were willing to participate in the Phase 3 study. These 10 patients did not differ from the 13 patients who refused to participate with respect to their clinical or exercise response to verapamil during Phase 1 or 2.

Long-term efficacy of verapamil (Phase 1 versus Phase 2): To determine the efficacy of verapamil over the 1 year follow-up, the clinical and exercise data of the 23 patients at the end of Phase 2 were compared with their initial results while taking placebo and verapamil, respectively, during Phase 1 (Table I). The improvement in the anginal attack rate, nitroglycerin consumed, and exercise duration while the patients were taking verapamil during Phase 1 continued to be demonstrated at the end of Phase 2.

The effects of verapamil on heart rate, blood pressure, and rate-pressure product were slightly different during Phase 1 and Phase 2. Heart rate at rest was significantly reduced compared with placebo during Phase 1, but not at the end of Phase 2. During submaximal exercise, heart rate, blood pressure, and rate-pressure product were significantly decreased with verapamil during Phase 1. At the end of Phase 2, however, only the heart rate during submaximal exercise differed from the placebo value. At maximum exercise, no differences were observed in heart rate, blood pressure, or rate-pressure product, while the patients were taking verapamil during either phase.

The effects of verapamil on the S-T segment response during exercise were similar during Phase 1 and at the end of Phase 2; both significant lengthening of the time

TABLE II Clinical and Exercise Results Comparing the 2-Week Periods After Withdrawal of Verapamil (Abruptly or Tapering) and the Initial Placebo Period

Variable	Placebo	Withdrawal		p value
		Abrupt	Tapering	
Clinical				
Anginal attacks per week	6.6 ± 7.8	7.8 ± 8.5	7.6 ± 8.1	NS
Duration of angina (min)	. . .	2.2 ± 0.6	2.6 ± 1.2	NS
Nitroglycerin tablets per week	7.8 ± 8.5	6.3 ± 7.4	5.8 ± 9.6	NS
Exercise test				
Exercise duration (s)	362 ± 94	338 ± 171	296 ± 116	NS
Onset S-T depression (s)	258 ± 75	266 ± 135	252 ± 96	NS
Peak S-T depression (mm)	2.0 ± 0.8	1.6 ± 0.8	1.8 ± 1.0	NS
Rate-pressure product ($\times 10^{-2}$)				
Rest	100 ± 13	107 ± 11	106 ± 16	NS
Submaximal exercise	152 ± 26	159 ± 19	157 ± 25	NS
Maximal exercise	204 ± 44	207 ± 30	193 ± 30	NS

NS = not significant.

to the onset of S-T segment depression and reduction of the peak S-T segment depression were observed at each time period. The peak S-T segment depression was further reduced at the end of Phase 2 compared with the value with verapamil during Phase 1 (1.2 ± 0.8 versus 1.9 ± 1.0 mm, respectively, $p < 0.05$).

Rechallenge with verapamil (Phase 1 versus Phase 3): During the third phase of the protocol, 10 patients were withdrawn from verapamil after 1 year of therapy, and then rechallenged in an 8-week double-blind, crossover, randomized, placebo-controlled trial. The data from these 10 patients during their Phase 1 studies were compared with their results during Phase 3. The mean number of anginal episodes and nitroglycerin tablets consumed while taking verapamil was reduced by 42 ± 38 and 55 ± 42%, respectively, during Phase 1 ($p < 0.05$), and by 63 ± 46 and 75 ± 53%, respectively, during Phase 3 ($p < 0.05$) (Fig. 2). Exercise duration during verapamil therapy was increased by 98 ± 21 seconds during Phase 1 ($p < 0.001$) and by 140 ± 40 seconds during Phase 3 ($p < 0.01$) (Fig. 3). The beneficial effects of verapamil on these clinical and exercise variables were similar during Phase 3 and in Phase 1 (p = NS).

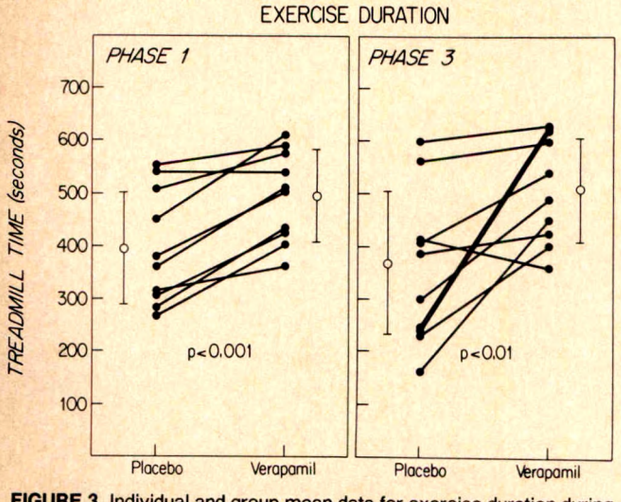

FIGURE 3. Individual and group mean data for exercise duration during the initial study (Phase 1) (**left**) and during the follow-up study (Phase 3) (**right**).

Abrupt withdrawal of verapamil (Table II): No patient had an unstable anginal syndrome or myocardial infarction during the 2-week period after the abrupt discontinuation of verapamil. There were no significant differences in either the number and duration of anginal attacks, the number of nitroglycerin tablets consumed, or the exercise response during the 2-week periods after abrupt cessation of verapamil compared with tapering of the drug. Moreover, there were no differences in the clinical and exercise responses when these 2 withdrawal periods were compared with the initial placebo period in the 10 patients.

Blood verapamil levels: Mean blood levels measured at the end of 2 weeks of verapamil therapy during Phase 1 were 298.1 ± 161.5 ng/ml (range 80 to 701) and during Phase 3 were 230.1 ± 119.3 ng/ml (range 61 to 467).

Discussion

Conventional drug therapy for the treatment of chronic stable angina has relied on the use of nitrate preparations[11,12] and beta-adrenergic blocking agents.[13,14] In some patients, however, intolerable adverse effects can occur.[15] Other patients have incomplete symptomatic relief even with combinations of these drugs. These considerations have led to a search for safe, alternative therapy for the treatment of angina pectoris.

The value of calcium-entry blocker drugs in treating patients with angina of effort has been demonstrated in numerous short-term, controlled trials.[1–8] The long-term efficacy and safety of verapamil in the treatment of angina pectoris, however, has not been well documented.

The present study shows that the benefits conferred by verapamil (480 mg/day) were maintained during a 1-year, open-label follow-up (Phase 2). Adverse effects from verapamil were minimal: constipation, remedied

by dietary adjustment or stool softeners and P-R interval prolongation on the resting electrocardiogram. None of these adverse effects required adjustment of the dosage of verapamil. Comparable beneficial actions of verapamil and paucity of adverse drug effects have been previously demonstrated when lower doses (360 mg/day) were given for 1 year.[16]

Verapamil achieved a similar reduction of anginal frequency and improvement in exercise tolerance during Phases 1 and 2. These beneficial effects have been attributed to a reduction in cardiac work,[4,8,16] mediated by a lower submaximal heart rate and rate-pressure product, findings corroborated in this study in both short-term (Phase 1) and long-term follow-up (Phase 2). Verapamil also caused a significant reduction of the peak S-T segment depression at a similar rate-pressure product, an effect which was greater at 1 year than at short-term follow-up. Less marked S-T segment depression at the same rate-pressure product may reflect enhancement of coronary perfusion to ischemic regions of myocardium.

The persistent beneficial effects of verapamil during Phase 2 at the end of 1 year in an open-label trial might have been due to spontaneous remission of angina pectoris, which has been observed to occur in up to one third of male patients,[17] rather than to the drug itself. To resolve this issue, a drug withdrawal and rechallenge study (Phase 3) was implemented 1 year after continuous verapamil therapy. Bala Subramanian et al[16] also performed a drug withdrawal study after 1 year of continuous verapamil therapy, in which exercise testing 4 weeks after reinstitution of placebo showed that there were no significant changes in the parameters analyzed compared with those on the initial placebo test. In contrast to the present study, the patients were not rechallenged with verapamil in a controlled protocol. The present investigation demonstrated that the patients had similar improvements in the symptomatic relief of angina pectoris and increased exercise duration when rechallenged with verapamil during Phase 3 as they had during the initial study in Phase 1. Thus, tachyphylaxis to verapamil did not occur, as has been suggested with nitrate therapy for the treatment of angina pectoris.[18,19] The persistent efficacy of verapamil appears due to the medication itself rather than to spontaneous disappearance of the anginal syndrome in the patients tested.

The beta-adrenergic blocking agents have been well documented as causing severe exacerbation of angina pectoris, myocardial infarction, and even sudden death when the drugs were abruptly discontinued.[20] This abrupt withdrawal syndrome may occur as late as 21 days after cessation of the medication.[21] Whether calcium-channel blocking agents may cause a similar exacerbation of ischemic events in patients with chronic stable angina is not known. One previous study did not note an exacerbation of anginal symptoms or myocardial infarction during a 1-week period when verapamil was withdrawn in 20 patients with chronic stable angina over a 3-day period.[22] In the present study, 10 patients were evaluated in a double-blind, crossover trial during both abrupt and gradual withdrawal from verapamil. None had unstable angina or myocardial infarction during abrupt cessation of verapamil. Moreover, anginal frequency and duration, nitroglycerin consumption, and exercise performance were similar during the 2-week evaluation periods after abrupt discontinuation of verapamil compared with its tapering (over 4 days), and when both withdrawal periods were compared with the initial placebo evaluation in the same patients.

The results of the present investigation demonstrate that verapamil is an effective and safe drug in the treatment of patients with stable angina pectoris. Sustained objective and subjective benefits from verapamil were seen for periods up to 1 year. Adverse effects from 480 mg/day of verapamil in this subpopulation of coronary patients were minimal. Abrupt withdrawal from verapamil was well tolerated and did not provoke unstable angina pectoris or myocardial infarction, as has been reported with beta-antagonist drugs.[20,21]

Enhanced Detection of Proximal Right Coronary Artery Stenosis With the Additional Analysis of Right Ventricular Thallium-201 Uptake in Stress Scintigrams

JACK GUTMAN, MB, BS, MICHAEL BRACHMAN, MD, ALAN ROZANSKI, MD, JAMSHID MADDAHI, MD, ALAN WAXMAN, MD, and DANIEL S. BERMAN, MD

The value of right ventricular thallium-201 analysis in detecting proximal right coronary artery stenosis in exercise myocardial scintigraphy was analyzed in 52 patients, 27 with and 25 without proximal right coronary artery stenosis. For the detection of proximal right coronary artery stenosis, the sensitivity and specificity of thallium scintigraphic analysis were 59 and 88% for a right ventricular abnormality, 67 and 68% for a left ventricular inferior wall abnormality, and 93 and 56% for an abnormality of either. When both right and left ventricular thallium images were abnormal, all 9 patients had proximal right coronary artery stenoses, and when both were normal, 26 of 28 patients had a normal proximal right coronary artery. The sensitivity and specificity of blood pool scintigraphic variables during exercise (right ventricular ejection fraction and left ventricular inferior wall motion) were not significantly different for detection of proximal right coronary artery stenosis.

Thus, the additional analysis of the right ventricle on thallium-201 stress scintigrams can improve the detection of proximal right coronary artery stenosis. When both right ventricular and left ventricular thallium scintigrams are abnormal (or normal), the ability to predict the presence (or absence) of proximal right coronary artery stenosis is very high.

Visual analysis of left ventricular (LV) stress thallium-201 scintigrams has been extensively studied and found to be clinically useful in detecting coronary artery disease.[1–7] Nevertheless, LV scintigrams have an inherent limitation in localizing individual coronary artery stenoses, especially those of the right coronary artery (RCA) and left circumflex artery.[2,3,6,7] However, the right ventricle has not been included in the analysis of these thallium-201 images. Recent observations showed that although the right ventricle is not usually visualized at rest, it is seen after exercise as well as in conditions associated with right ventricular (RV) hypertrophy, and RV volume and pressure overload.[8–10] Right ventricular visualization has been related to an increase in RV myocardial blood flow.[11]

Subsequent to our initial observation[12] and the establishment of criteria[13] for RV thallium defects after stress in patients with coronary artery disease, this study was undertaken to evaluate the usefulness of RV thallium scintigraphic analysis in the detection of proximal RCA stenosis. In addition, we compared the ability of 2 blood pool scintigraphic variables, RV ejection fraction[14–17] and LV inferior wall motion,[18] during sequential 2-view exercise, to detect proximal RCA stenosis.

Methods

Patient population: The study consisted of 52 patients with a history of chest pain who were referred to our cardiac stress laboratory because of suspected or known coronary artery disease. There were 43 men and 9 women with a mean age of 55 years (range 24 to 82). Of these, 11 had previous myocardial infarction, including 6 inferior and 5 anterior infarctions (Q wave ≥0.04 second), on electrocardiography. All patients underwent stress-redistribution thallium-201 myocardial scintigraphy, exercise blood pool scintigraphy, stress

electrocardiography, and cardiac fluoroscopy within 3 months of coronary arteriography.

Forty-six patients had coronary artery disease (defined as ≥50% reduction in diameter) on coronary angiography. Of these, 27 had triple-, 8 had double-, and 11 had single-vessel coronary artery disease (only 1 with isolated RCA stenosis). Six patients had normal coronary angiograms. Thirty-two patients had RCA stenosis, including 27 with stenosis proximal to the acute margin (Group I) and 5 with more distal stenosis (Group II). Twenty patients had either normal or <50% stenosis of the RCA (Group III). The sensitivity for the detection of proximal RCA stenosis was determined from Group 1 and the specificity from Groups II and III.

Exercise protocol: Thallium-201 scintigraphy was performed after treadmill exercise according to the Bruce protocol with continuous 12-lead electrocardiographic monitoring. Equilibrium blood pool scintigraphy was performed during upright bicycle exercise with a graded work load starting at 25 W and increasing every 3-minute stage by an additional 25 W. Imaging was performed in the last 2 minutes of exercise in each stage.

Exercise was maximal, terminated only for exhaustion or the development of severe angina, serious arrhythmia, or hypotension. At maximal exercise during treadmill thallium scintigraphy and during upright bicycle blood pool scintigraphy, heart rates (mean ± standard deviation) were 150 ± 26 and 148 ± 19 beats/min (p = not significant) and systolic blood pressures (mean ± standard deviation) were 171 ± 27 and 195 ± 26 mm Hg, respectively (p <0.001). All patients on beta-blocking drugs were asked to withold this medication for 24 to 48 hours before exercise testing.

Thallium-201 scintigraphy: A dose of 2 mCi of thallium-201 was injected intravenously at near maximal treadmill exercise, and exercise was continued an additional 45 to 60 seconds. Serial, multiple-view myocardial scintigrams were obtained, beginning approximately 6 minutes (immediate poststress imaging) and 3 to 5 hours (redistribution imaging) after the injection of thallium. For each phase of imaging, 10-minute images were obtained in the anterior and 45° and 70° left anterior oblique projections. Imaging was performed using a standard field-of-view Anger camera equipped with 37 photomultiplier tubes, an 0.25 inch thick sodium iodide crystal, and a high-resolution parallel-hole collimator. A 25% energy window centered on the 80 keV X-ray peak and another independent 15% window centered on the 167 keV photopeak were used. All scintigrams were recorded on Polaroid film with a triple-lens camera.

The thallium images from each patient were examined jointly by 2 experienced observers without knowledge of the clinical history or results of coronary angiography. For both the poststress and 4-hour redistribution scintigrams, the inferior wall of the left ventricle in each of the anterior and 70° left anterior oblique views and the right ventricle in the 45° left anterior oblique view were divided into 2 segments. Thallium activity was visually assessed for each region by a 4-point scoring system: 0 = normal, 1 = slightly decreased but almost normal, 2 = definitely decreased, and 3 = severely decreased. Differences in scores were mediated by consensus. For the left ventricle a perfusion defect was defined by a segmental score of at least 2. For the right ventricle a perfusion defect was considered present if a comparative difference in thallium-201 uptake of at least 1 score occurred between the 2 segments or if a marked diminution or absence of thallium-201 uptake occurred in both segments. Because of the differences in muscle mass and regional blood flow between the right and left ventricle, the left ventricle was not used as an absolute guide when assessing RV thallium uptake. Thus, small relative differences in thallium activity between the right and left ventricle were considered normal.

Blood pool scintigraphy: Multiple-gated equilibrium blood pool scintigraphy was performed as follows: after the intravenous injection of 25 mCi of in vitro labeled autologous technetium-99m red blood cells, data were acquired with a portable scintillation camera (Picker) equipped with a parallel-hole, low-energy, all purpose collimator and a dedicated minicomputer (A^2 Medical Data Systems). During each 2-minute acquisition period, the computer divided the scintigraphic data from each cardiac cycle into 20 frames. An average of 100,000 counts per frame was collected using a 25% energy window centered on the 140 keV photopeak of technetium-99m. Exercise imaging was first performed in the 40° to 50° left anterior oblique view and, after a 20- to 30-minute rest period, was repeated in the anterior view.[19] For the anterior view, a 5° to 10° caudal tilt was employed if it provided a better separation of the right and left ventricles. During exercise, a foam wedge was inserted into the space between the obliquely angulated scintillation camera and the patient, and the patient was then strapped to the scintillation camera to minimize patient motion.

The determination of RV ejection fraction involved light pen assignment of 2 regions of interest over the right ventricle in the left anterior oblique view, 1 in end-systole and the other in end-diastole, and then dividing the stroke counts (end-diastolic counts − end-systolic counts) by background-corrected end-diastolic counts.[14]

Left ventricular inferior wall motion was assessed in the anterior view using a 5-point scoring system (−1 = dyskinesia, 0 = akinesia, 1 = severe hypokinesia, 2 = mild hypokinesia, and 3 = normal).[20]

The right ventricular ejection fraction response to exercise was considered normal if the exercise ejection fraction increased by at least an absolute 5% from the resting value. Left ventricular inferior wall motion was analyzed by the consensus of 2 experienced observers unaware of any clinical informa-

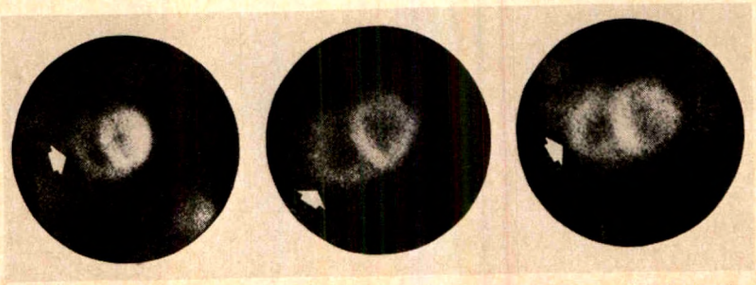

FIGURE 1. Normal right ventricular stress thallium scintigrams (**arrows**) in the 45° left anterior oblique view in 3 patients with a normal right coronary artery.

tion, and was considered abnormal when the wall motion score at maximal exercise was <3. Inferior segments obscured by RV overlap were excluded from analysis.

Assignment of RCA territory to scintigraphic images: Both segments of the RV image on the thalllium-201 scintigrams and the right ventricle on the blood pool scintigrams were considered to represent the distribution of the proximal RCA. The LV inferior wall of the thallium-201 scintigrams (anterior and 70° left anterior oblique views) and the inferior wall of the blood pool scintigrams (anterior view) were considered to represent the distribution of either the proximal or the distal RCA.

Coronary arteriography: Selective coronary arteriography was performed in multiple views using the Judkins technique. The RCA was divided into 2 segments, 1 proximal and the other distal to the acute margin of the heart. Each coronary angiogram was graded by 2 observers who were unaware of the results of noninvasive testing. Significant stenosis was considered present when there was ≥50% diameter narrowing of the RCA. Of the 52 patients who had coronary angiography, 10 patients had a nondominant RCA; 6 had left dominant systems and 4 had balanced systems. Both the RCA and left circumflex coronary artery had significant stenoses in 4 of the 10 patients, and both the RCA and left circumflex coronary artery were normal or had insignificant stenoses in 6 patients.

Statistical analysis: McNemar's test was used to assess the significance of the difference in sensitivity and specificity between RV and LV scintigraphic analysis in the detection of proximal RCA stenosis.[21] Whenever the expected cell frequencies were <5, the binomial test was used. A p value <0.05 was considered significant.

Results

Sensitivity and specificity of thallium-201 scintigraphy: Sixteen of 27 Group I patients were considered abnormal by visual assessment of RV thallium-201 images (sensitivity 59%). Right ventricular thallium-201 scintigrams showed nothing abnormal in all 5 patients in Group II and in 17 of 20 in Group III (specificity 88%).

For detection of a proximal RCA stenosis, LV thallium-201 scintigraphy resulted in a sensitivity of 67% (18 of 27 in Group I were considered abnormal) and a specificity of 68% (2 of 5 in Group II and 15 of 20 in Group III). These results were not significantly different from those on RV analysis. When either RV or LV thallium-201 scintigraphic techniques were abnormal, 25 of 27 patients (93%) in Group I were detected (p <0.01 compared with RV or LV thallium-201 images analyzed separately). The specificity of the combined analysis was 14 of 25 or 56% (p <0.05).

When only concordant RV and LV scintigrams were analyzed, all 9 patients who had both abnormal RV and LV thallium-201 images had proximal RCA stenosis. Conversely, of 28 patients with both normal RV and LV scintigrams, 26 had a normal proximal RCA. Of the 6 patients with inferior myocardial infarction, 3 had abnormal RV and 6 had abnormal LV thallium scintigrams. Representative LV and RV thallium scintigrams of patients with and without a proximal RCA stenosis are illustrated in Figures 1 to 4.

Comparison of blood pool scintigraphic variables: Fifteen of 27 Group I patients had an abnormal RV ejection fraction response to exercise (sensitivity 56%), whereas 4 of 5 patients in Group II and 12 of 20 in Group III had a normal response (specificity 64%). For detection of a proximal RCA stenosis, analysis of the LV inferior wall at peak exercise resulted in a sensitivity of 59% (16 of 27 Group I patients) and a specificity of 64% (3 of 5 Group II and 13 of 20 Group III patients). Neither the sensitivity nor the specificity of RV ejection fraction or inferior wall motion differed significantly from RV thallium analysis for the detection of proximal RCA stenosis.

When both RV ejection fraction and LV inferior wall motion were analyzed, the sensitivity was 81% (22 of 27 Group I patients) (p <0.05) and the specificity 48% (3 of 5 Group II and 9 of 20 Group III patients) (p <0.05). Of 14 patients with abnormal RV ejection fraction and LV inferior wall motion, only 9 had proximal RCA stenosis, and of 28 patients with both normal RV ejection fraction and LV inferior wall motion, 23 had a normal proximal RCA. Two of 6 patients with inferior myocardial infarction had abnormal RV ejection fractions, and 6 of 6 had abnormal LV inferior wall motion.

Discussion

Detection of proximal RCA stenosis: The results of the present study demonstrate that the addition of analysis of the RV to the inferior LV wall of stress thallium-201 images improves sensitivity in the detec-

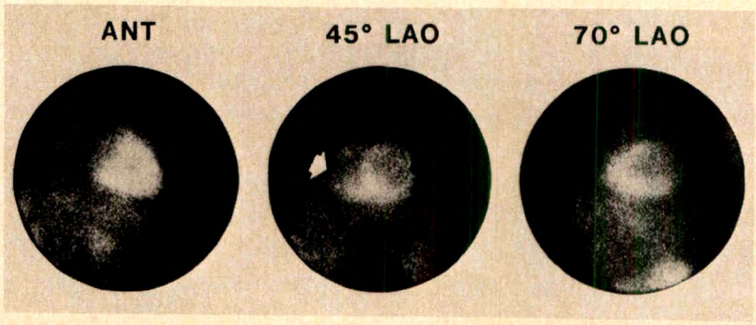

FIGURE 2. Proximal defect (**arrow**) in the right ventricular stress thallium scintigram in the 45° left anterior oblique view (LAO) of a patient with a proximal right coronary artery (RCA) stenosis. Of note, the inferior wall of the left ventricle in both the anterior (ANT) and 70° left anterior oblique view has normal thallium uptake. This is an example of a proximal RCA stenosis detected by right but not left ventricular inferior wall analysis.

tion of proximal RCA stenosis. Although the sensitivity of RV and LV thallium scintigrams was not significantly different, their combined analysis did improve the ability to detect proximal RCA stenosis, with a decrease in specificity. For exercise blood pool scintigraphy, the sensitivity for the detection of proximal RCA stenosis also improved when the analysis of RV ejection fraction and LV inferior wall motion was combined.

Until recently the interpretation of stress thallium scintigrams has been limited to the left ventricle for the detection of RCA stenosis. In previous studies, the results that were obtained (sensitivity between 50% and 73%) are similar to those of our study when analysis of the left ventricle only was performed.[2,3,6,7,22] Two other recent reports have also described the use of RV thallium-201 scintigrams to detect proximal RCA stenosis. The first of these was performed at rest during vasodilation with dipyridamole.[23] In this study, the sensitivity and specificity were similar to those we described, again with improvement in sensitivity from 60% when the left ventricle was analyzed to 93% when the RV was also assessed. However, the other experiment, performed with exercise, showed only a small nonsignificant change in sensitivity from 67% for LV inferior wall imaging to 78% for both RV and LV scintigrams.[24]

Of potential clinical importance is the predictive ability of the concordant interpretation of both RV and LV scintigrams. When the thallium images of the right and left ventricle were normal, the proximal RCA was normal in 93% of patients and, conversely, when both scintigrams were abnormal, there was a proximal stenosis in 100% of cases. These results of concordant thallium-201 scintigraphic interpretations again agree with the results of RV and LV imaging after dipyridamole when the combination of normal RV and LV inferior wall distribution of thallium was highly predictive for the absence of a proximal RCA stenosis.[23] In the exercise thallium-201 study abstracted by Brown et al,[24] 75% of patients with both normal RV and LV images had neither a proximal nor a distal RCA stenosis. This percentage is lower than ours and may be due to the inclusion of distal RCA stenosis in their analysis.

In contrast to thallium analysis, concordant results of blood pool scintigraphy were not as accurate. When both RV ejection fraction and LV inferior wall motion were normal, the proximal RCA was normal in 82%. However, when both were abnormal, proximal RCA stenosis was found in only 64%.

Perhaps the most important limitation in the assessment of thallium uptake in the RV free wall is that common to the visual analysis of LV thallium scintigrams, that is, the subjective variation in the interpretation of defects.[22] In the future, quantitation of the initial distribution and washout of thallium-201,[25] if applied to the right as it has been to the left ventricle, may decrease the subjectivity of this analysis.

Clinical implications: Our study indicates that the previously reported suboptimal sensitivity for the de-

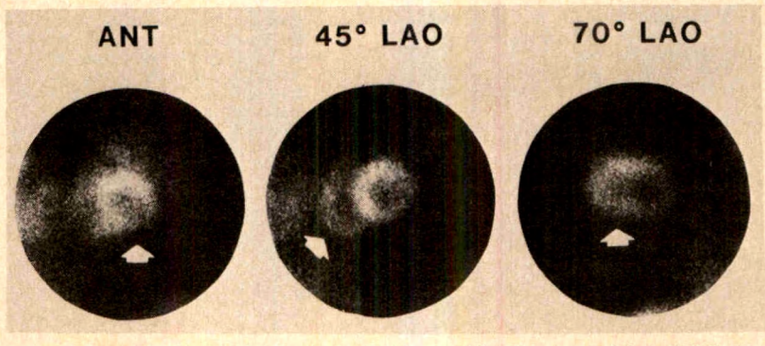

FIGURE 3. Left ventricular inferior wall stress defects in the anterior (ANT) and 70° left anterior oblique (LAO) views (**arrows**) in a patient with a proximal right coronary artery stenosis. Normal right ventricular thallium uptake in the 45° LAO view (**arrow**) is noted.

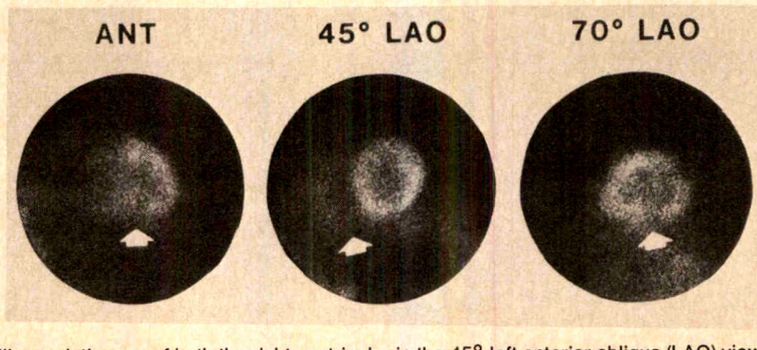

FIGURE 4. Defects in the thallium scintigrams of both the right ventricular in the 45° left anterior oblique (LAO) view (**arrow**) and the inferior wall of the left ventricle in the anterior (ANT) and 70° LAO views (**arrows**) of a patient with a proximal right coronary artery stenosis. This pattern is highly predictive of a proximal right coronary artery stenosis.

tection of individual coronary artery stenoses with the visual analysis of stress thallium scintigrams can be improved to detect proximal RCA stenosis by the additional interpretation of RV thallium uptake. The assessment of RV thallium uptake may improve the ability to detect patients with multivessel coronary disease using stress thallium-201 scintigraphy, which is limited by the low sensitivity for detecting RCA and left circumflex coronary stenoses.[6]

Prognostic and Predictive Value of Exertional Hypotension In Suspected Coronary Heart Disease

K. E. HAMMERMEISTER, MD, TIMOTHY A. DeROUEN, PhD,
HAROLD T. DODGE, MD, and MAY ZIA, MS

The prognostic and predictive value of exertional hypotension was assessed in 1,241 patients having treadmill maximal exercise testing, coronary arteriography, and follow-up averaging 5.4 years. Medically treated patients with coronary artery disease (CAD) with exertional hypotension had poorer survival than did those without such hypotension; however, maximum systolic pressure during exercise was a more powerful predictor of survival. Patients with exertional hypotension had more extensive CAD and more left ventricular (LV) dysfunction than did patients who had an increase in blood pressure with exertion; these findings probably account for the impaired survival. However, exertional hypotension, was an insensitive indicator of significant left main coronary artery stenosis, 3-vessel disease, or severe resting LV dysfunction.

The normal response to upright dynamic exercise such as walking or running is an increase in systolic pressure as measured by a cuff at the arm.[1,2] Exertional hypotension, defined here as a decrease in exercise systolic pressure below resting systolic pressure, is commonly considered an ominous finding and an indication for invasive evaluation. Previous studies have shown a strong association of exertional hypotension with multivessel coronary artery disease (CAD)[3,4] and a likelihood of the development of ventricular fibrillation if exercise is continued.[5] However, the late prognostic significance of exertional hypotension in relation to other commonly used noninvasive and invasive prognostic indicators has not been reported. This study assesses the prognostic value of this variable both univariately and multivariately in a population of patients with suspected CAD. The sensitivity and predictive power of exertional hypotension in detecting critical CAD and resting left ventricular (LV) dysfunction in a large coronary arteriography registry are also reported.

Methods

The characteristics of the Seattle Heart Watch Angiography Registry have previously been described in detail.[6,7] Briefly, all 5 hospitals in Seattle in which coronary arteriography is being performed agreed to enter patients undergoing this procedure for suspected CAD into a prospectively followed registry with the primary goal of identifying patients at risk for sudden cardiac death. Between 1969 and 1974 inclusively, 733 initially medically treated patients and 1,881 surgically treated patients were entered into this registry.

The extensive baseline characterization of these patients included data items from the history, physical examination, resting electrocardiogram, chest film, maximal treadmill exercise test (Bruce protocol[8]), coronary arteriogram, and quantitative angiographic assessment of LV function. Patients were exercised to symptom-limited maximum, although a decrease in systolic blood pressure during submaximal exercise was commonly used as an indication for physician termination of testing. Blood pressure was measured near the end of each 3-minute stage of exercise by arm cuff. The only significant complication of exercise testing in this series occurred in a single patient who required cardioversion for ventricular tachycardia.

The decision in regard to medical versus surgical therapy was made by the patient's physician or physicians on the basis of clinical findings and the results of the coronary arteriogram. Follow-up in regard to death and nonfatal cardiovascular endpoints occurred at 6-month intervals by mailed questionnaire; mean follow-up was 5.4 years with maximum follow-up >10 years.

The initial portion of this report giving baseline characteristics and survival analyses of patients with and without exertional hypotension is restricted to the 557 initially med-

ically treated patients who had maximal treadmill exercise testing at the time of entry into this registry. For analyses of baseline characteristics predictive of exertional hypotension and sensitivity, specificity, and risk ratios of exertional hypotension in detecting critical coronary stenoses or severe LV dysfunction, data in all 1,241 patients (medically and surgically treated) with exercise testing were used.

Comparison of baseline characteristics between patients with and those without exertional hypotension was performed using the chi-square test for discrete variables and Student's *t* test for continuous variables. A stepwise logistic regression analysis was used to identify patients in whom exertional hypotension was likely to develop and specifically to test the effect of propranolol on the development of exertional hypotension. The survival of patients with and those without exertional hypotension was calculated by the life-table technique,[9] with differences in survival tested by the Mantel-Haenszel-Cox statistic.[10] The hypothesis that exertional hypotension is an independent predictor of survival after adjusting for other baseline characteristics was tested using Cox's regression analysis which assumes a proportional hazards model.[11] Sensitivity, specificity, and risk ratio were calculated as follows, where TP = true positives, FP = false positives, TN = true negatives, and FN = false negatives: sensitivity = TP/(TP + FN); specificity = TN/(TN + FP); risk ratio = [TP/(TP + FP)] × [(FN + TN)/FN].

Results

Characteristics of patients with exertional hypotension: Tables I and II compare the baseline characteristics between the 35 medically treated patients with and the 522 without exertional hypotension. In general, patients with exertional hypotension were more symptomatic, had poorer exercise performance, had more CAD, and poorer LV function. The frequency of propranolol use was not significantly different between patients with exertional hypotension (24%) and those without it (17%). The mean decrease in systolic pressure from resting to submaximal or maximal exercise was 19 mm Hg in the exertional hypotension subgroup compared with a 41 mm Hg increase in the subgroup without exertional hypotension.

Prognostic value of exertional hypotension: Figure 1 compares the actuarial survival of medically treated patients with and without exertional hypotension. The 5-year survival probability for patients with exertional hypotension is 0.71 ± 0.08, but is 0.88 ± 0.02 for patients without exertional hypotension. The difference between the 2 curves is highly significant (chi-square = 8.529; p <0.001).

The prognostic value of exertional hypotension and maximum systolic pressure during exercise in relation to other noninvasive variables was studied using Cox's regression analysis (Table III). Noninvasive variables significantly predictive of survival of medically treated patients in order of their level of significance are: a history of congestive heart failure, cardiac enlargement detected on chest film, maximum systolic pressure during exercise, S-T segment depression on resting electrocardiogram, age, and any ventricular arrhythmia on the resting electrocardiogram. When adjusted for the simultaneous prognostic effect of maximum systolic pressure and these other variables, exertional hypotension is not predictive of survival. We also tested the prognostic significance of exertional hypotension, adjusting only for the 2 most powerful predictors from the history: congestive heart failure and age. Using the Cox model, exertional hypotension is not significantly predictive of survival (p = 0.075) when adjusting only for these 2 variables.

Characteristics predictive of exertional hypotension: To identify variables independently predictive of the development of exertional hypotension, the statistically significant variables in Tables I and II (exercise variables were excluded)

End-systolic volume (ml/m^2)	421	32.8 ± 25.8	27	42.9 ± 27.1	<0.05
Ejection fraction	453	59.0 ± 15.7	28	50.9 ± 15.6	<0.01

ETT = exercise tolerance test; n = number of patients in whom variable was measured; p = significance of difference between means; SD = 1 standard deviation.

plus propranolol use were entered into univariate and multiple logistic analyses. The results are shown in Table IV. Although propranolol use was not univariately associated with exertional hypotension (neither in the chi-square analysis nor in the univariate logistic model), it and LV contraction grade were the only 2 variables significantly associated with exertional hypotension in the multivariate model.

Predictive value of exertional hypotension: The relation between exertional hypotension and left main coronary artery stenosis ≥50% diameter reduction, 3-vessel disease (stenoses ≥70%), and severe resting LV dysfunction (ejection fraction ≤30%) is shown in Table V. Although left main coronary disease and 3-vessel disease are significantly more frequent in patients with exertional hypotension, the use of this variable alone detected only a minority of patients with these coronary lesions. The proportion of patients exhibiting exertional hypotension who have ejection fractions ≤30% (5 of 81, 6%) is not significantly different from the proportion of

N = 787 (65 with exertional hypotension).

patients without exertional hypotension who have low ejection fractions (37 of 937, 4%).

For the detection of patients with left main coronary artery stenosis ≥50%, exertional hypotension has a sensitivity of 15% (15 of 101), a specificity of 93% (1,051 of 1,127), and a risk ratio of 2.18 to 1. Similarly, for the detection of patients with 3-vessel disease (stenoses ≥70%), exertional hypotension has a sensitivity of 15% (42 of 271), a specificity of 95% (919 or 970), and a risk ratio of 2.26:1. Finally, for the detection of severe left ventricular dysfunction (ejection fraction ≤30%), the findings are similar: sensitivity 12% (5 of 42), specificity 92% (900 of 976), and risk ratio 1.56 to 1. The high specificities are a reflection of the relatively low prevalence rates of left main coronary artery stenosis, 3-vessel disease, and severe left ventricular dysfunction in the total population. These data should not be interpreted to mean that the absence of exertional hypotension gives any reliability of the absence of these 3 conditions.

Discussion

Exertional hypotension, which was prevalent in the Seattle Heart Watch Angiography Registry in 7.5% (93 of 1,241) of patients having exercise tests, is associated with more severe symptoms, more advanced CAD, and greater LV dysfunction. In a multivariate logistic analysis LV contraction grade and propranolol use were the only 2 variables significantly associated with the development of exertional hypotension. When examined alone, exertional hypotension is an indicator of impaired prognosis; however, when tested in the multivariate Cox model, the correlated variable, maximum systolic pressure with exertion, is a better predictor of survival. Exertional hypotension is an insensitive technique to identify patients with critical CAD or severe resting LV dysfunction.

The prevalence of exertional hypotension depends on the nature of the population being studied and the methods of exercise testing, including criteria for termination of exercise. Morris et al[4] reported no occurrence of exertional hypotension in 560 clinically normal male subjects and in only 1 of 159 patients with chest pain syndrome and normal coronary arteriograms. The latter findings are similar to data from our Seattle Heart Watch Arteriography Registry in that only 3 of 221

TABLE V Relation of Exertional Hypotension to Left Main Coronary Stenosis (≥50%), 3-Vessel Disease (Stenoses ≥70%), or Severe Left Ventricular Dysfunction (Ejection Fraction ≤30%) in Medically and Surgically Treated Patients With Coronary Arteriography

N = number of patients with 3-vessel disease or left main stenosis; T = total number of patients with exertional hypotension undergoing coronary arteriography.

patients (1.4%) with suspected CAD but normal coronary arteriograms (no stenosis ≥70%) had exertional hypotension. Irving et al[14] document a progressively decreasing maximum systolic pressure on exertion with increasing extent of CAD. Anderson et al[15] report an abnormal exercise blood pressure response (exertional hypotension in 6; decreasing systolic pressure in 10) in 16 of 25 patients with left main coronary artery stenosis ≥50%. Among our medically treated patients the prevalence of exertional hypotension increased from 7.4% (12 of 163) in patients with single-vessel disease to 10% (11 of 111) in patients with 2-vessel disease and to 18% (9 of 50) in patients with 3-vessel disease. Although the likelihood of having exertional hypotension clearly increases with increasing extent of coronary disease, the reported prevalence in patients with 3-vessel disease ranges from 16 to 73%, and from 4 to 35% in patients with left main coronary artery stenosis (Table VI). Despite the wide range of prevalence, the likelihood of

3-vessel disease or left main coronary stenosis in patients with exertional hypotension is sufficiently high (50%; 47 of 93 in the present series) to warrant careful attention. If other obvious causes of exertional hypotension are not present (obstructing valve lesions, obstructive cardiomyopathy, hypotension occurring at very high work loads, or propranolol use, as subsequently described), coronary arteriography probably should be performed, particularly because patients with these coronary artery lesions have prolonged survival with surgical therapy.[16,17]

Exertional hypotension, however, cannot be relied on to detect patients with 3-vessel disease or significant left main stenosis as the sensitivity is very low (15%). Most (85%) patients with these critical lesions will not exhibit exertional hypotension. Weiner et al[18] report low sensitivities very similar to ours in the detection of patients with left main coronary artery stenosis (21%) and 3-vessel disease (24%). The data of Irving et al[14] suggest that the requirement of a decrease in exercise blood pressure below the resting level is too stringent a test for the detection of 3-vessel disease. Their 180 patients with 3-vessel disease had an average increase in systolic pressure during exercise of about 20 mm Hg, even though this increment was less than half that in the 85 patients without significant CAD on arteriography. Dell' Arciprete et al[19] report that 60% of patients with multivessel disease (including 9 of 10 with significant left main coronary artery stenosis) had a maximum increase in systolic pressure with bicycle exercise ≤40 mm Hg. Using a less strict definition of abnormal exertional blood pressure response (failure to increase 10 mm Hg or more or an initial increase and then a decrease ≥20 mm Hg), Sanmarco et al[20] report a higher sensitivity of 39% in the detection of 3-vessel or left main CAD. Specificity was still high at 87%. Thus, the use of a subnormal increment in systolic pressure with exertion is a clinically more useful tool to select patients at high risk for left main CAD or 3-vessel disease than is exertional hypotension.

Left ventricular dysfunction as measured by the contraction grade is more strongly associated with exertional hypotension than with the extent of CAD, as the latter variable drops out in the multivariate logistic analysis. Although contraction grade and ejection fraction are highly correlated, the former, based on a subjective assessment of LV contraction patterns, seems to be a better predictor of exertional hypotension. We have used the scale of I to V described by Hamilton et al[21] in which I is normal and V is generalized hypokinesia or akinesia involving ≥75% of the ventricular circumference.

Even though propranolol is not univariately associated with exertional hypotension, the multivariate logistic model documents a significant relation between propranolol use and the development of exertional hypotension when simultaneous adjustment is made for LV function and the other variables in Table III. Exertional hypotension developing in patients taking propranolol may be the result of the drug and not necessarily of more extensive disease. We would not recommend that the development of exertional hypotension in patients on full doses of propranolol be used as the sole indication for invasive studies.

As shown in Figure 1, exertional hypotension is an indicator of impaired prognosis in this population of nonoperated patients having both exercise testing and coronary arteriography and including patients with and without significant CAD. In another analysis confined to nonoperated patients with significant CAD (stenoses ≥50%), exertional hypotension was not significantly predictive of survival.[22] Exertional hypotension appears to be a more powerful predictor of prognosis in populations in which the presence or absence of CAD is unknown, than in populations with proven CAD. This fact is presumably due to the uncommon occurrence of exertional hypotension in patients without CAD (other types of heart disease excluded) and the good prognosis of these patients.

In our multivariate analyses, maximum systolic pressure with exertion was a more powerful predictor of survival than exertional hypotension, as has been previously reported by Irving et al[14] and Bruce et al.[23] In our analyses confined to nonoperated patients with significant CAD, the maximum pressure-rate product was a significant predictor of prognosis even after adjustment for the invasively determined variables, ejection fraction and number of obstructed coronary arteries.[22]

In conclusion, quantitative measures of the physiologic response to exertion (maximum systolic blood pressure and pressure-rate product) are important prognostic indicators, in addition to both clinical and invasive measures, of cardiac function. However, exertional hypotension, defined as a decrease in exercise systolic blood pressure below resting levels, is too insensitive an indicator of extensive disease or impaired prognosis, or both, to be relied on as a screening test, even though its presence may be ominous.

Acknowledgment: We thankfully acknowledge the contributions of Drs. John A. Murray and Robert A. Bruce for their efforts in Seattle Heart Watch planning and execution and the cardiologists and cardiac surgeons in Seattle who contributed data on their patients. The comments of Drs. Robert A. Bruce and Richard P. Anderson have been helpful in the preparation and presentation of these analyses. Also, the efforts of Barbara Buck, Rose Fontanilla, Verona Hofer, and Gladys Petit have been invaluable.

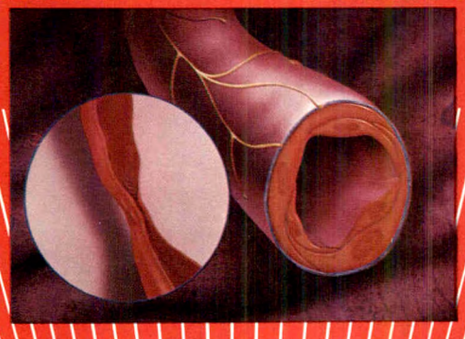
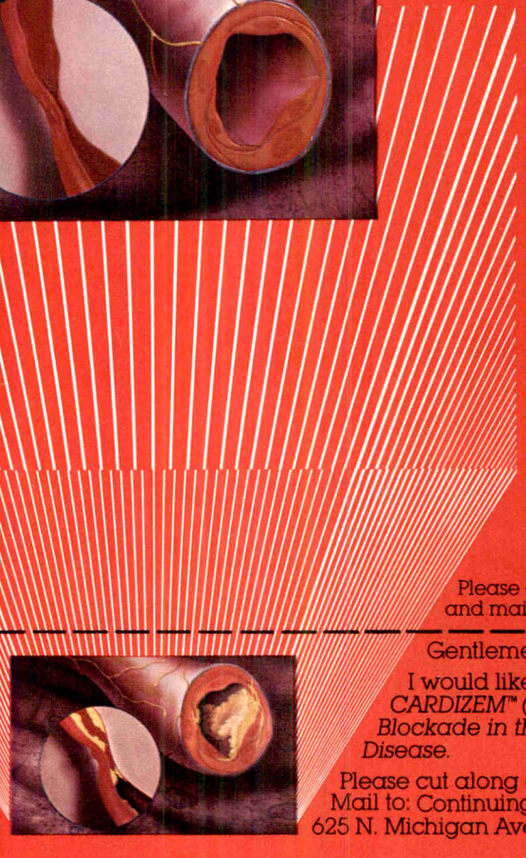
An educational program on new dimensions in the treatment of angina.*

CARDIZEM™ (diltiazem HCl): Calcium Channel Blockade in the Treatment of Coronary Heart Disease.

The CARDIZEM™ (diltiazem HCl) Educational Program will include a 30-minute film, with animated highlights depicting major aspects of the new class of drugs known as calcium channel blockers. To facilitate understanding of the use of calcium antagonists, a full monograph/self-test will accompany the film. Authorities in the fields of cardiology, pharmacology, and medicine will discuss the impact calcium channel blockers can make in the treatment of angina.





Please complete and mail this coupon for information.

Gentlemen:

I would like to arrange a showing of *CARDIZEM™ (diltiazem HCl): Calcium Channel Blockade in the Treatment of Coronary Heart Disease.*

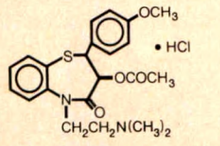
PROFESSIONAL USE INFORMATION

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanism of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (4 of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem t.i.d. of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely, and enzymes were nearly normal a week after cessation of treatment. No rechallenge was carried out, but the patient had no evidence of viral hepatitis and received no other drugs but isosorbide dinitrate.

   No other similar liver injury has been reported in clinical trials, but marketing experience in Europe has resulted in a rechallenge-confirmed instance of hepatocellular injury. However, it should be noted that there have been further episodes of raised transaminases in the absence of diltiazem in this patient, so that the relationship to diltiazem of the abnormalities is not completely clear. Other instances of transaminase elevation have been reported in Europe, but their relationship to drug is uncertain.

PRECAUTIONS

General. CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect of diltiazem on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-blockers or digitalis is currently being investigated in well-controlled studies.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. Experience with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), and fatigue (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of presentation corresponds to the relative frequency of occurrence.

Cardiovascular:	Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart.
Central Nervous System:	Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations.
Gastrointestinal:	Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis.
Dermatologic:	Pruritus, petechiae, urticaria.
Other:	Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and safety of dosages exceeding 240 mg per day are currently being investigated. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents.

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

Writing with care for CHF:

Avoid any change in the classic digitalis-Lasix® regimen.

BRAND OF (furosemide)

9 out of 10 cardiologists specify LASIX® (furosemide) by brand name.* And 2 out of 3 take the extra step to prevent substitution.*

7 out of 10 cardiologists also specify the leading brand of digoxin.* Both are part of the classic LASIX®-digitalis regimen.

In the same survey,* LASIX® and the leading brand of digoxin were named more often than any other agent, in any therapeutic class, as drugs for which these cardiologists would *never* allow generic substitution. Both were prescribed by brand name more often than any other drug.

LASIX®—specified for good reason.

Especially in CHF, precision is crucial. Any therapeutic variable could easily upset the sensitive digitalis/diuretic/electrolyte balance and precipitate digitalis toxicity.

LASIX®, the most thoroughly documented drug in its class, offers quality so consistent that almost 8 billion tablets have been manufactured without a single product recall. In more dosage strengths and forms than any other diuretic. Good reason for the cardiologists surveyed to say they prescribe LASIX® more frequently than all other diuretic agents they named.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

*National survey of 2960 physicians, including 1502 cardiologists and other physicians subspecializing in cardiology, conducted by Hoechst-Roussel Pharmaceuticals Incorporated, Somerville, New Jersey. August, 1982.

The diuretic of choice in CHF.

BRAND OF (FUROSEMIDE)

Rx

Specify LASIX® brand of furosemide. To be sure the patient receives only LASIX®, take the steps necessary on your prescription to prevent substitution, in accordance with the regulations of your state.

Lasix 40mg #60
Sig. 1 b.i.d.
Do Not Substitute

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

MYTH: Fluid-filled catheters are an inexpensive and dependable means of measuring patient blood pressure.

FACT: When accurate patient diagnosis is at stake, "inexpensive" can be costly. Catheter-tip pressure transducers give substantially better accuracy and patient information at a *lower cost per use.*

There is a myth in the medical community that fluid-filled catheters are less expensive to use than catheter-tip pressure transducers.

But that myth is deceiving. The purchase price of a fluid-filled, disposable catheter can be one-seventh that of a reusable, catheter-tip pressure transducer.[1] But the catheter-tip pressure transducer can often give you twenty-five or more uses.[2] So, when the cost of use and not just the purchase price alone is examined, the "more expensive" catheter-tip pressure transducer is actually about half the cost per use of the fluid-filled catheter.

[1]Based on a Millar catheter-tip pressure transducer (Model PC-350).

[2]With the Millar MIKRO-TIP® pressure transducer with the new MT-10™ sensor, multiple usage is greatly increased. The new MT-10™ sensor sets the standard for ruggedness and durability in catheter-tip pressure transducers.

Accuracy and dependability bring the true cost of a catheter-tip pressure transducer even lower. With Millar MIKRO-TIP® catheter-tip transducers, you get an accurate reading the first time. Valuable man-hours are saved, and even more savings are available due to the increased number of measurements that can be performed.

With Millar MIKRO-TIP® catheter-tip transducers, you can forget:

- Time-consuming debubbling[3] of the measuring system before catherization can begin
- Contending with a complicated, often messy, and usually inconvenient fluid-filled system
- Damping of the pressure signal due to changes of the fluid in the tubes, or air infiltration of the system
- Disturbance of the signal and, consequently, less accurate blood pressure measurements caused by the position of the transducer or movement of the patient

What you can depend on is easy-to-use, consistent, dependable, accurate readings of blood pressure — at the source — and at a cost per use much lower than you've been led to believe.

[3]i.e. debubbling tubing, stopcock connection, etc.

30 mg
capsules

(temazepam)

A more appropriate half-life

One 30-mg capsule, h.s.—*usual adult dosage.*
One 15-mg capsule, h.s.—*recommended initial dosage for elderly and/or debilitated patients.*

INDICATIONS AND USAGE: Restoril® (temazepam) is indicated for the relief of insomnia associated with complaints of difficulty in falling asleep, frequent nocturnal awakenings, and/or early morning awakenings. Since insomnia is often transient and intermittent, the prolonged administration of Restoril is generally not necessary or recommended. Restoril has been employed for sleep maintenance for up to 35 consecutive nights of drug administration in sleep laboratory studies.

The possibility that the insomnia may be related to a condition for which there is more specific treatment should be considered.

CONTRAINDICATIONS: Benzodiazepines may cause fetal damage when administered during pregnancy. An increased risk of congenital malformations associated with the use of diazepam and chlordiazepoxide during the first trimester of pregnancy has been suggested in several studies. Also, ingestion of therapeutic doses of benzodiazepine hypnotics during the last weeks of pregnancy has resulted in neonatal CNS depression. Restoril is contraindicated in pregnant women. Consider a possibility of pregnancy when instituting therapy or whether patient intends to become pregnant.

WARNINGS: Patients receiving Restoril (temazepam) should be cautioned about possible combined effects with alcohol and other CNS depressants.

PRECAUTIONS: In elderly and/or debilitated patients, it is recommended that initial dosage be limited to 15 mg. The usual precautions are indicated for severely depressed patients or those in whom there is any evidence of latent depression; it should be recognized that suicidal tendencies may be present and protective measures may be necessary.

If Restoril is to be combined with other drugs having known hypnotic properties or CNS-depressant effects, due consideration should be given to potential additive effects.

Information for Patients: Patients receiving Restoril should be cautioned about possible combined effects with alcohol and other CNS depressants. Patients should be cautioned not to operate machinery or drive a motor vehicle. They should be advised of the possibility of disturbed nocturnal sleep for the first or second night after discontinuing the drug.

Laboratory Tests: The usual precautions should be observed in patients with impaired renal or hepatic function. Abnormal liver function tests as well as blood dyscrasias have been reported with benzodiazepines.

Pregnancy: Pregnancy Category X. See Contraindications.

Pediatric Use: Safety and effectiveness in children below the age of 18 years have not been established.

ADVERSE REACTIONS: The most common adverse reactions were drowsiness, dizziness and lethargy. Other side effects include confusion, euphoria and relaxed feeling. Less commonly reported were weakness, anorexia and diarrhea. Rarely reported were tremor, ataxia, lack of concentration, loss of equilibrium, falling and palpitations. And rarely reported were hallucinations, horizontal nystagmus and paradoxical reactions, including excitement, stimulation and hyperactivity.

Restoril is a controlled substance in Schedule IV. Caution must be exercised in addiction-prone individuals or those who might increase dosage.

DOSAGE AND ADMINISTRATION: *Adults:* 30 mg usual dosage before retiring; 15 mg may suffice in some. *Elderly and/or debilitated:* 15 mg recommended initially until individual response is determined.

SUPPLIED: Restoril (temazepam) capsules—15 mg maroon and pink, imprinted "RESTORIL 15 mg"; 30 mg, maroon and blue, imprinted "RESTORIL 30 mg". Packages of 100, 500 and ControlPak® packages of 25 capsules (continuous reverse-numbered roll of sealed blisters). (RES-Z2 11/1/81)

Before prescribing, see package insert for full product information.

SANDOZ, INC.
East Hanover, NJ 07936

NITRODISC™

(NITROGLYCERIN)

5 mg/24 hr
10 mg/24 hr discs

DESCRIPTION: Nitrodisc incorporates a patented Microseal Drug Delivery™ system consisting of a solid, nitroglycerin-impregnated polymer bonded to a flexible, non-sensitizing adhesive bandage. It is designed to be applied topically. Nitrodisc provides constant and controlled drug delivery over a uniform skin surface area for 24 hours.

Nitrodisc is available in two strengths which release either 5 mg or 10 mg of nitroglycerin during a 24-hour period. The 5 mg/24 hr system contains 16 mg nitroglycerin over an 8 cm^2 releasing surface. The 10 mg/24 hr system contains 32 mg nitroglycerin over a 16 cm^2 releasing surface.

INDICATIONS AND USAGE: Nitrodisc is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Nitrodisc (nitroglycerin) is contraindicated in patients known to be intolerant of organic nitrate drugs, and in patients with marked anemia, increased intraocular pressure, or increased intracranial pressure.

WARNINGS: In patients with acute myocardial infarction or congestive heart failure, Nitrodisc should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of patients with angina, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent potential withdrawal reactions, which are characteristic of all vasodilators in the nitrate class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness, or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Nitrodisc is not intended for immediate relief of anginal attacks. For this purpose, occasional use of sublingual preparations may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Nitrodisc therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, Nitrodisc (nitroglycerin) dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION: Nitrodisc should be applied once each day. To use Nitrodisc, follow the instructions on the package. Nitrodisc should be applied to an intact skin site free of hair and not subject to excessive movement. It should not be applied to the distal parts of the extremities. A suitable area should be shaved free of hair, if necessary. The application site should be changed slightly each time to avoid undue skin irritation. A new Nitrodisc should be applied if the product loosens.

The optimal dosage regimen should be selected based upon the clinical response, the side effects, and the effects of therapy upon blood pressure and heart rate. It is recommended that therapy be initiated with the smaller Nitrodisc, and that the larger Nitrodisc be utilized when a greater response is desired. In the event that higher doses are necessary, multiple pads may be applied.

THE NEW QUANTUM™ PACEMAKER

8mm THIN

And in better shape than ever.

MORE PHYSIOLOGICALLY COMPATIBLE SHAPE.
The new thin oval shape of the model 253-19 unipolar Quantum is designed to fit more comfortably into a smaller pocket with less tissue irritation. No upward cut into the fascia is necessary, and the pacemaker stays more securely in place.

LESS HASSLE—A NEW INTER-LOCK™ LEAD CONNECTOR SYSTEM.
The model 253-19 incorporates the innovative Inter-Lock™ lead connector system. This new, easy-to-use system requires no set screw assembly and allows leads to connect quickly and easily into place without the handling of loose screws or caps.

SMALLER SIZE, SAME FULL QUANTUM CAPABILITIES.
The model 253-19 unipolar Quantum 8mm features the same advanced measured telemetry, full multiprogrammability and transtelephonic capabilities as our other Quantum pacemakers.

The new, more convenient unit houses the same proven circuitry that makes Quantum a complete patient management system. Over 10,000 prescription programming combinations plus measured telemetry allow the physician to adjust the pacemaker to the patient's changing needs. Both operating and programmed data are available in digital read-out or hard copy form to help in making better, faster clinical decisions.

The unique new connector system, plus the thinner, lighter, more physiologically compatible shape of the new Quantum pacemaker, is another example of Intermedics' commitment aiding the physician in providing better patient care. As part the complete Quantum Pacing System, the 8mm thin model 253-19 represents continuing progress in technological advancements for better patient management.

QUANTUM INDICATIONS AND CONTRAINDICATIONS

The indications for cardiac pacing are increasing as pacemakers become more sophisticated and as advance methods for patient management become more widespread. Generally accepted indications for long-term cardiac pacing include, but are not limited to: (1) sick sinus syndrome; (2) chronic, symptomatic drug-resista sinus arrhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) block as seen in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bundle branch block; and (7) hypersensitive carotid sinus syndrome (carotid sinus syncope). In addition, certain patients presenting st symptoms as intractable, recurrent congestive heart failure; cerebral or renal insufficiency; or recurrent drug- resistant tachyarrhythmias, and who have been shown to benefit from temporary cardiac pacing, are conside candidates for permanent cardiac pacing.

The indications for permanent pacing in cases of acute myocardial infarction have not yet been rigorously defined. Factors to be considered include the location of the myocardial infarct, the presence or absence of symptoms, ventricular rate, the mechanism of arrhythmias, and response to therapy. In general, symptomati drug-resistant bradyarrhythmias that impair cardiac output are considered indications for pacing in patients v acute myocardial infarction, regardless of infarct location.

There are no known contraindications to the use of pacemakers as a medical method for control of heart rat

Effects of a Cardioselective Beta$_1$ Partial Agonist (Corwin) On Left Ventricular Function and Myocardial Metabolism in Patients With Previous Myocardial Infarction

MICHEL F. ROUSSEAU, MD, HUBERT POULEUR, MD,
and MARIE-FRANÇOISE VINCENT, MD

Corwin is a new selective beta$_1$ partial agonist, able to stabilize the beta$_1$ adrenoceptors at approximately 43% of their maximal activity. The aim of the study was to determine the effects of this agent in patients with coronary artery disease (CAD) and previous myocardial infarction (MI). In a first group of 14 patients, corwin increased significantly the peak (+)dP/dt (+35%; $p < 0.005$), the global ejection fraction, and the ejection fraction of abnormally contracting segments (from 20 ± 18 to 26 ± 19%; $p < 0.02$). Corwin also induced significant decreases in mean systolic (−8%; $p < 0.05$) and mean diastolic (−38%; $p < 0.001$) wall stress and accelerated the relaxation rate. In a second group of 11 patients, a metabolic study indicated that neither myocardial oxygen consumption (15 ± 7 versus 15 ± 7 ml/min; difference not significant) nor lactate extraction was modified by the drug. In this group, increases in peak (+)dP/dt, acceleration in ventricular relaxation (−8 ms in time constant of isovolumic pressure decrease; $p < 0.01$), and decreases in left ventricular end-diastolic pressure also were noted after administration of corwin, both under basal conditions and during a cold pressor test. In conclusion, corwin is a positive inotrope which, in patients with CAD and left ventricular dysfunction, improves left ventricular systolic and diastolic function without inducing myocardial ischemia.

Impairment in left ventricular (LV) systolic and diastolic performance is common in patients with coronary artery disease (CAD),[1] but the optimal medical management of such abnormalities still remains to be defined. Indeed, inotropic agents such as catecholamines are frequently deleterious when oxygen supply is limited,[2–4] and potentially harmful side effects have also been reported with digitalis[5] and vasodilators[6] in this setting.

Recently, as a possible safe alternative to cardiac glycosides and catecholamines, an orally active beta$_1$ adrenoceptor agonist (ICI 118,587,* corwin) has been developed.[7–10] When compared with epinephrine, this compound has 2 major differences. First, it is devoid of beta$_2$ vasodilator effects and of metabolic effects such as effects on glucose metabolism.[7,8] Second, corwin is only a partial beta$_1$ agonist. A partial agonist is a compound that possesses both agonist and antagonist properties.[11] In terms of its intrinsic sympathomimetic activity, a partial agonist is only able to produce a fraction (approximately 43% in the case of corwin) of the maximal response of a full agonist such as isoprenaline. Conversely, in the presence of a sufficient concentration of a partial agonist, the effects of a full agonist will be antagonized. Therefore, because of these characteristics it appeared that corwin might improve the function of the chronically ischemic myocardium, which is likely to be depleted in catecholamines,[12] while minimally affecting the normal myocardium.

Furthermore, because corwin narrows the range over which the sympathetic nerves may modulate cardiac

* (±)-1-(4-hydroxyphenoxy)-3-[2-(4-morpholinecarboxamido)ethylamino]-propan-2-ol, hemifumarate.

function,[7,9] it could also be useful each time sympathetic drive is inadequate. This situation may occur not only during sleep, when a low sympathetic stimulation frequently exacerbates heart failure, but also during exercise or emotion; indeed, in some patients an excessive sympathetic tone during exercise may be responsible for inappropriate tachycardia and myocardial ischemia. Therefore, the aim of the present study was to determine first whether corwin could significantly improve LV systolic and diastolic function in patients with a previous myocardial infarction (MI). In addition, considering the importance of the balance between oxygen supply and demand in this setting, the metabolic effects of corwin were also analyzed both under basal conditions and when the heart was stressed by a cold pressor test. The results suggest that this compound can improve cardiac function without inducing myocardial ischemia.

Methods

Twenty-five patients with significant CAD and a previous MI were included in this study. All were in sinus rhythm and underwent diagnostic cardiac catheterization; none had valvular disease. Clinical data, MI location on electrocardiography, and angiographic data are listed in Table I. All cardioactive drugs, listed in Table I, were discontinued at least 72 hours before the procedure. Each patient gave informed consent, and no complication resulted from this study.

Two experimental protocols were used. In protocol I, the effects of corwin on LV systolic and diastolic function were assessed in 14 consecutive patients (patients 1 to 14 in Table I) using LV angiography. In protocol II, performed in 11 consecutive patients with anterior MI (patients 15 to 25 in Table I), the changes in coronary blood flow, myocardial oxygen consumption, and lactate and hypoxanthine extraction together with the changes in plasma epinephrine and norepinephrine were determined before and after administration of corwin, both under basal conditions and during a cold pressor test. Patients with anterior MI were selected for this protocol to ensure that the blood samplings and flow measurements made in the coronary sinus were representative of myocardial areas with perfusion defects.

Experimental protocol I: Left heart catheterization was performed using the femoral approach with the patient in the fasting state and without premedication. High fidelity LV pressures were recorded with a 5Fr micromanometer-tipped catheter (Millar Instruments). Aortic pressure was measured through an 8Fr pigtail catheter connected to a Statham P23ID strain gauge. Hemodynamic data were first measured under basal conditions. Then, control left ventriculography was performed using single plane 35 mm cineangiography at 50 frames/s in the right anterior oblique projection (Philips Poly-Diagnost C). The hemodynamic variables and a cineangiographic frame marker were recorded on magnetic tape (Honeywell 101) and on paper (Honeywell 1858).

Five minutes after control ventriculography, 0.1 mg/kg of corwin was injected intravenously over a 5-minute period. Hemodynamic variables were recorded 15 minutes after the end of corwin administration. Studies in healthy volunteers have indeed shown that peak inotropic effects were already reached at this time and were thereafter maintained for 4 to 6 hours.[10] A second ventriculographic procedure was performed 25 minutes after the first, when the depressant effect of contrast material should have disappeared. After this procedure, coronary arteriography was performed using the Judkins technique.

Measurements and computations of protocol I: Analog data filtered at 100 Hz were digitized every 2 ms and processed off-line by means of a Hewlett-Packard 2113E computer. The first derivative of the LV pressure was computed after digital filtering with a recursive method implementing a sixth order Butterworth type low-pass filter with a band width of 50 Hz (−3 db). Specific points on the signals (such as the peak of the R wave) were automatically detected during at least 3 respiratory cycles, and to minimize respiratory effects, hemodynamic measurements were made at end-expiration. The time constant T_1 of the exponential LV pressure decrease during the first 40 ms after peak (−)dP/dt was used as an index of isovolumic LV relaxation.[13]

The technique used to analyze LV angiograms was previously reported in detail.[14,15] Midwall circumferential stress was calculated by the formula of Sandler and Dodge[15]: Stress = $[Pb/H]\ [1 - b^3/a^2\ (2b + H)]$, where P = LV pressure, H = wall thickness, a mid-wall semimajor axis, and b = mid-wall semiminor axis. Ejection fraction and mean velocity of fiber shortening were calculated according to the standard formula. Volume data were corrected for body surface area, and end-systolic or end-diastolic volumes were defined, respectively, as the smallest and largest LV volumes obtained. Mean systolic wall stress was determined by averaging the data from the start to the end of the ejection, and mean diastolic wall stress was obtained by averaging the data from the start of ventricular filling to the peak of the R wave.

To assess the LV properties during early diastolic filling, angiographic and hemodynamic data were also analyzed during the period of decreasing ventricular elastance, that is, when the LV pressure is decreasing or remaining constant despite an increase in ventricular volume. To evaluate the ventricular elastance during this phase and to allow comparisons before and after corwin administration, a standardized incremental LV elastance ($\Delta P/\Delta V$, units: mm Hg/ml/m^2) was computed as described previously.[14]

To evaluate regional systolic function, the end-diastolic and end-systolic silhouettes were superimposed by aligning the long axis (mid-aortic valve to apex) and fixing the center of gravity. Five angular segments were defined from this midpoint, beginning at the left aortic valve margin. The change of area of each segment, corresponding to a segmental ejection fraction, was determined as follows: (end-diastolic area − end-systolic area)/(end-diastolic area) × 100. The normal range of segmental ejection fraction for each segment was determined in a group of 15 normal subjects. This normal group was previously reported,[15] and these normal values were used to classify the segmental ejection fraction of the present patients as normal (included within the normal range) or abnormal (below the lowest normal limit).

Experimental protocol II: Left heart catheterization and hemodynamic data analysis were performed as in protocol I. In addition, a 7Fr Swan-Ganz thermodilution catheter (Webster Laboratories) was placed in the mid-coronary sinus through an antecubital vein. The position of this catheter was confirmed angiographically and by oxygen saturation (average 4.7 ml/100 ml, range 2.8 to 7.1) and checked regularly with fluoroscopy. Coronary sinus flow was measured by the continuous thermodilution method of Ganz et al.[16] Heart rate, LV and aortic pressure, and coronary sinus blood flow were continuously recorded first under control conditions and during a cold pressor test (patient's hand immersed in ice water for 3 minutes). When hemodynamic data had returned to basal values, corwin (0.1 mg/kg) was given as described. Fifteen minutes after the end of corwin injection, data were again recorded under basal conditions and a similar cold pressor test was performed (Fig. 1). Arterial and coronary venous blood were drawn during each step. During both cold

C_1 and CPT_1 = control and control cold presso test; C_2 and CPT_2 = control and cold pressor test afte treatment with corwin. The treatment with corwin clearl decreased left ventricular pressure during diastole. Val ues of peak (+)dP/dt were, respectively: 1,657, 1,923 1,737, and 1,843 mm Hg/s. All beats were selected a end-expiration. ECG = electrocardiogram.

pressor tests, the presented hemodynamic data were obtained at the end of the first minute, just before blood sampling.

Biochemical measurements: For lactate and hypoxanthine measurements, 3 ml of whole blood was deproteinized immediately with an equal volume of ice-cold 10% (weight/volume) $HClO_4$ containing 0.6 nmol of (8-^{14}C) hypoxanthine. Lactate was determined according to Hohorst.[17] Hypoxanthine measurements were performed by high-performance liquid chromatography.[18] Plasma for catecholamine assay was immediately frozen and catecholamines were measured as described by Mefford et al.[19]

Statistical analysis: Comparison of the data of protocol I before and after corwin was performed using a paired *t* test. Comparison of the serial data of protocol II was performed using repeated-measure analysis of variance.[20]

Results

Protocol I: LV function: Table II summarizes the effects of corwin on LV systolic function. After corwin, the heart rate increased slightly in 9 patients (+6 beats/min for the whole group; $p < 0.05$) and peak (+)dP/dt increased in all patients from 1,732 to 2,334 mm Hg/s ($p < 0.005$). LV end-diastolic pressure declined in 8 patients, whereas end-diastolic volume decreased in 9; at the group level, these changes were insignificant. End-systolic volume index decreased from 58 to 53 ml/m^2 ($p < 0.05$) and the global ejection fraction was moderately improved. A small decrease in mean systolic wall stress (−8%; $p < 0.05$) was also noted despite a trend toward increasing LV systolic pressure.

Figure 2 illustrates 2 typical examples of the changes in wall motion after corwin administration. The changes in global ejection fraction generally were attended by an increase in segmental ejection fraction in the abnormal segments, but a decrease in the percentage of shortening of normal areas was sometimes observed. Therefore, in individual patients, it was very difficult to determine which changes corresponded to a real deterioration or improvement and which were artifacts (such as noise on LV silhouette or displacement of the reference point). To minimize the artifacts, therefore, the segments were pooled according to their classification as normal or abnormal. When all normal segments were pooled, no change in segmental ejection fraction was evident: 55 ± 14% during control versus 56 ± 17% after corwin administration (n = 43 normal segments; difference not significant [NS]). In contrast, the segmental ejection fraction of the pooled abnormal segments was significantly increased from 20 ± 18% to 26 ± 19% (n = 27 abnormal segments; $p < 0.02$).

Corwin also ameliorated LV relaxation as indicated by a faster rate of isovolumic pressure decrease (peak [−]dP/dt and T_1: Table III) and by a 38% decrease in mean diastolic wall stress ($p < 0.001$). Incremental LV elastance during early filling was impaired under basal conditions (−0.48 mm Hg/ml/m^2 versus −0.95 in normal subjects; $p < 0.01$)[14] but returned to normal values after corwin administration (Table III).

After corwin administration, the cardiac output values derived from angiographic data increased in the whole group by 9% ($p < 0.05$); patients with an ejection

fraction <55% tended to have a greater increase in output (+23%) than did those with a normal ejection fraction. The increase in cardiac output was confirmed by direct measurement (Fick principle) in 4 patients with depressed ejection fraction; cardiac index increased in all from 2.9 ± 0.8 to 3.9 ± 0.9 liters/min/m^2. No significant changes in mean aortic pressure (96 ± 9 versus 104 ± 13 mm Hg; NS) or diastolic aortic pressure (68 ± 12 versus 74 ± 8 mm Hg; NS) were noted. Calculated systemic vascular resistance decreased from 1,467 ± 459 to 1,160 ± 200 dynes·s/cm^5 ($p < 0.05$).

Protocol II: myocardial metabolism: An example of the hemodynamic changes observed in this protocol is given in Figure 1, and Table IV summarizes hemodynamic and metabolic changes both under basal conditions and during the cold pressor tests.

As in the first protocol, corwin significantly increased peak (+)dP/dt and accelerated LV relaxation under control conditions. In this group, heart rate increased in only 5 patients and decreased in 6. Interestingly, the patients who had an increase in heart rate had the lowest resting rates: 71 ± 14 versus 80 ± 14 beats/min ($p < 0.05$). LV end-diastolic pressure decreased in all patients an average of 6.3 mm Hg ($p < 0.01$). Beneficial effects on LV performance were also present during the cold pressor test. Indeed, corwin allowed the left ventricle to meet the same pressure load at a markedly lower end-diastolic pressure (22.9 versus 31.4 mm Hg; $p < 0.05$) than during the control cold pressor test. Peak (+)dP/dt and relaxation were also significantly im-

IGURE 3. Individual values of myocardial oxygen consumption ($M\dot{V}O_2$) efore and after administration of corwin (ICI). CPT = cold pressor ıst.

roved when this maneuver was performed after corwin dministration (Table IV).

No significant change in coronary blood flow or resistance was observed after corwin administration. As own in Figure 3, myocardial oxygen consumption was mparable before and after the drug. The severity of ıe coronary lesions did not seem to influence the results. After corwin administration, arterial lactate decined in 9 patients, remained constant in 1, and increased from 403 to 577 nmol/ml in the last patient. Thus, there was a tendency for arterial lactate to decrease after the drug (from 582 ± 129 to 526 ± 108 mol/ml; $p < 0.08$). Despite this reduction in lactate vailability, no significant change in myocardial lactate xtraction or consumption was observed (Table IV). It ıould be emphasized that lactate production was not bserved after corwin administration in any patient. inally, no change in hypoxanthine levels was noted in ıe coronary sinus after the drug (Table IV), and the rteriovenous difference in hypoxanthine also remained :able (average 0.018 ± 0.48 nmol/ml before and 0.052 0.50 after the drug; NS).

Arterial plasma levels of norepinephrine obtained in) patients averaged 1.45 ± 0.71 pmol/ml under basal nditions and were not modified after corwin administration (1.52 ± 0.95 pmol/ml; NS). Arterial norepiephrine levels increased in 9 of 10 patients during the ntrol cold pressor test to 2.16 ± 1.44 pmol/ml ($p < 0.1$ ersus control) and to 2.19 ± 1.44 pmol/ml ($p < 0.1$ ersus control) during the corwin cold pressor test. The ntrol myocardial arteriovenous difference in norepiephrine averaged −0.43 ± 0.92 pmol/ml, with 6 paents showing myocardial release of norepinephrine. fter corwin administration, this arteriovenous difrence increased in all patients up to 0.31 ± 0.84 mol/ml. Arterial plasma epinephrine was stable during ıe 4 successive steps of the protocol (0.78 ± 0.39; 0.83 0.41; 0.83 ± 0.41, and 0.91 ± 0.49 pmol/ml; NS) and change in myocardial arteriovenous difference was bserved.

Comparison of the response to corwin in protools I and II: Despite the fact that consecutive patients ere studied, global LV function appeared more dressed in the patients in protocol II. Indeed, patients in protocol II had generally higher end-diastolic pressure and lower ejection fraction than did patients in protocol I. To ensure that corwin had produced comparable effects in both situations, a separate analysis was performed, considering only the response of patients with an ejection fraction of 40 to 55%. Seven patients in protocol I (mean control ejection fraction 48 ± 6%, increasing significantly to 53 ± 7% after corwin) were thus compared with 6 patients in protocol II (mean control ejection fraction (48 ± 6%). When the data of such patients with similar LV dysfunction were considered, corwin evidently had produced similar increases in peak (+)dP/dt (+477 ± 358 versus +440 ± 250 mm Hg/s; group I versus group II: NS) and an identical acceleration in relaxation rate (T_1 −9 ms in both groups) in the 2 experimental protocols. Furthermore, LV end-diastolic pressure declined in all 6 patients in group II and in 5 of the 7 patients in group I, and the absolute changes in end-diastolic pressure were not significantly different (−6 ± 5 versus −2 ± 4 mm Hg; NS).

Discussion

Our data indicate that corwin is a positive inotrope that improves LV function in patients with ischemic heart disease without significant effects on coronary blood flow or myocardial metabolism.

Effects of corwin on LV inotropic state: The changes in peak (+)dP/dt were used to assess the variations in inotropic state. This index is indeed very sensitive to acute changes in myocardial contractility and is little affected by preload changes.[21] Furthermore, because LV preload never increased after corwin and because peak (+)dP/dt increased even in patients with an unchanged heart rate, the increases in peak (+)dP/dt evidenced after corwin undoubtedly reflect a true positive inotropic effect.[21] Small quantitative variations were observed in the response to corwin: peak (+)dP/dt tended to increase more in protocol I and LV end-diastolic pressure declined more sharply in protocol II. However, such differences disappeared when patients with similar impairment in LV function were compared. Therefore, it is likely that these small variations were caused by the fortuitous discrepancy in ventricular function rather than by a different response to corwin. In addition, the artifactual increase in circulating blood volume caused by the contrast material may also have blunted the filling pressure decrease in protocol I.

In the presence of myocardial infarction and LV dyssynergy, however, peak (+)dP/dt and ejection phase indexes only represent global parameters. Accordingly, such indexes might simply reflect a positive inotropic stimulation of normal areas whereas hypokinetic zones could remain unchanged or even be adversely affected. To evaluate the effects of corwin on chronically ischemic zones, changes in segmental ejection fraction were analyzed. Our results indicate that abnormal sectors were generally improved and that enhanced shortening of the abnormal zones was an important determinant of the improvement in global ejection fraction. Animal experiments have established that excessive inotropic

stimulation frequently results in a functional deterioration of the hypoperfused areas.[2] Although perfect wall motion analyses are difficult in individual subjects, the foregoing results nevertheless suggest that the inotropic stimulation of corwin was sufficiently moderate to avoid such side effects. Finally, this increased inotropic state favorably influenced ventricular geometry during ejection, thereby reducing mean systolic wall stress. Here also we recognize that stress computation is subject to errors in the presence of MI. Accordingly, the stress figures must only be considered as indicative of directional changes.

In our small group of patients, an increase in cardiac output attended by a moderate decrease in systemic vascular resistance was present after corwin administration, and this increase was more evident in patients with abnormal ejection fraction. Similar changes have been reported by Simonsen[22] in patients with moderate heart failure. Nevertheless, others have observed insignificant changes in cardiac output and vascular resistance after administration of this drug to patients with a previous infarct but with normal ventricular function.[23] This last result suggests that the decrease in vascular resistance passively follows the increased flow. Further studies are needed to determine to what extent the cardiac output response is dependent on the degree of impairment in ventricular function.

Effects of corwin on LV relaxation and diastolic filling: Abnormalities in LV relaxation and diastolic filling are common in patients with CAD.[1,13,24] Recent studies have correlated these relaxation abnormalities with the presence of viable but chronically ischemic myocardium.[1,13] Some investigators suggest that these impairments in relaxation not only may decrease coronary perfusion but also may produce clinical manifestations of heart failure by altering ventricular compliance and filling pressures.[25] In this perspective, the effects of corwin on this phase of the cardiac cycle, which are different from those of cardiac glycosides, may be clinically important. First, by facilitating early diastolic filling and by decreasing LV end-diastolic pressure, corwin may reduce signs of pulmonary congestion during stress (Fig. 1) and improve the functional status of the patient. Secondly, by increasing the rate of isovolumic relaxation and by decreasing mean diastolic wall stress, corwin is likely to improve coronary perfusion particularly in the subendocardial layers. This in turn might relieve some myocardial ischemia responsible for impairment in systolic and diastolic function. Therefore, part of the enhanced shortening of hypokinetic areas might be related to this second mechanism rather than to direct inotropic stimulation.

Effects of corwin on myocardial metabolism: An important observation is that corwin neither significantly increased myocardial oxygen consumption nor significantly modified lactate or hypoxanthine metabolism. Several factors may explain the lack of change in oxygen consumption and the absence of ischemia. First, the decrease in mean systolic wall stress contributed to the reduced myocardial oxygen demand and could have compensated for the increase in oxygen demand associated with $beta_1$ stimulation. Second, as discussed herein, coronary perfusion of ischemic areas may have been preserved or even enhanced by the improvement in relaxation and by the decrease in mean diastolic wall stress.[25] This increased coronary perfusion could prevent the development of ischemia and lactate or hypoxanthine production in the abnormal zones. Finally, an important point could be the magnitude of the agonist activity of corwin. Although the dose used was at the top of the dose-response curve in human subjects,[9,10] the increases in peak (+)dP/dt were smaller than those observed with dobutamine[3,4] or prenalterol.[26] Both dobutamine and prenalterol possess greater beta agonist activity but have been shown to increase myocardial oxygen consumption,[3,4,26] which in the case of dobutamine may have been responsible for myocardial ischemia.[3,4] Therefore, the limited inotropic effect of corwin is an important safety factor for future clinical application.

Another property of corwin is its tendency to decrease arterial lactate. This contrasts with the increase in arterial lactate observed during catecholamine administration.[4] This particular property probably resides in its lack of $beta_2$ metabolic effects. One consequence is that the lactate availability as substrate to the heart is reduced, which can explain the discrete, insignificant reduction in lactate extraction.[27] To ensure that such a small reduction in lactate extraction was not related to a limited myocardial ischemia, the hypoxanthine production was also checked. Indeed, previous studies have suggested that hypoxanthine release was sometimes more pronounced than lactate release during ischemia.[28] The absence of any change in hypoxanthine handling further suggests that any significant ischemia can be excluded.

Clinical implications of a selective $beta_1$ partial agonist: Corwin has a dual pharmacologic action, namely, it acts as a $beta_1$ agonist when the sympathetic tone is low and as a $beta_1$ antagonist when the sympathetic tone exceeds its partial agonist activity. In other words, corwin stabilizes the sympathetic stimulation of the heart at a level equal to its partial agonist activity, that is, approximately 43% of the activity of the full agonist isoprenaline.

In severe heart failure refractory to classic therapy, the acute administration of a partial agonist may not bring major advantages over a carefully titrated infusion of a full agonist such as dopamine. The pharmacology of these compounds suggests that they may produce deleterious hemodynamic effects when administered in patients with high plasma levels of catecholamines. Consequently, it is more likely that corwin will be clinically useful primarily in patients with moderate heart failure (class II to III, New York Heart Association), who still have normal plasma concentrations of catecholamines at rest. In this clinical setting, they offer a novel opportunity to stabilize the function of the heart at a level of inotropic stimulation sufficient to keep an adequate pump function in the presence of ventricular dysfunction. As already pointed out, a partial agonist should also buffer the myocardium from potentially harmful decreases or increases in sympathetic tone, as may occur during sleep or exercise, respectively.

om such stabilization of the inotropic state.

Patients with CAD and significant LV dysfunction ight perhaps be among the best indicators of such artial agonists. Many patients with MI cannot receive eta-blocking agents, and it was recently suggested that igitalis could also be detrimental in this setting.[5] Accordingly, a partial agonist, which is able to antagonize xcessive sympathetic stimulation[7,9,23] and at the same me prevent myocardial depression and inappropriate radycardia, might open interesting therapeutic perpectives. Similarly, in other forms of heart failure with oderately elevated cardiac filling pressures at rest, a artial agonist appears to improve resting hemodyamic function and exercise tolerance.[29] In such cases, partial agonist could also prevent the frequent exacbations of pulmonary congestion during the night hich not only are related to the supine position but also ay be caused by the decreased sympathetic drive uring sleep.[30] Further studies are needed to evaluate e effects of such agents on functional capacity and to etermine whether changes in $beta_1$ adrenoceptor umber or sensitivity might occur after their prolonged dministration, resulting in tachyphylaxis.

In conclusion, in patients with CAD and ventricular ysfunction, corwin improves cardiac function and efciency without inducing myocardial ischemia. herefore, considering its lack of arrhythmogenic acvity[23] and its property to antagonize deleterious effects f high levels of circulating catecholamines,[7,9,23,29] rwin represents a promising inotropic drug in the ifficult setting of ischemic heart disease.

Relation of Segmental Wall Motion to Global Left Ventricular Function in Acute Myocardial Infarction

FUMITAKA OHSUZU, MD, CHARLES A. BOUCHER, MD, JOHN B. NEWELL, BA, TSUNEHIRO YASUDA, MD, HERMAN K. GOLD, MD, ROBERT C. LEINBACH, MD, KENNETH A. McKUSICK, MD, ROBERT D. OKADA, MD, SIMON ROSENTHAL, PhD, GERALD M. POHOST, MD, and H. WILLIAM STRAUSS, MD

The relation of left ventricular regional wall motion to global ventricular function was evaluated by radionuclide ventriculography in 127 patients within 18 hours of acute myocardial infarction. No patient had evidence of previous myocardial infarction. The following parameters were measured: (1) wall motion index; (2) percent of abnormally contracting segment; (3) ejection fraction (EF); (4) end-diastolic volume (EDV) and end-systolic volume (ESV); and (5) peak systolic cuff pressure/end-systolic volume ratio (PSP/ESV). The measurements of global function correlated well with wall motion index ($r = 0.83$, $p < 0.001$ for EF; $r = -0.69$, $p < 0.001$ for ESV; and $r = 0.061$, $p < 0.001$ for PSP/ESV), but EDV correlated less well ($r = -0.35$, $p < 0.001$). Multiple linear regression analysis revealed that EF correlated best with wall motion index, and no other parameters of global left ventricular function added significantly to the regression.

The correlation of motion in each segment with EF was determined by multiple linear regression analysis. Ejection fraction correlated best with motion in the anterobasal, then in order of correlation, in the apical-septal, inferoapical, anterolateral, and superlateral walls. The relation of EDV, ESV, and degree of percent abnormally contracting segments was as follows: EDV did not increase with a mild regional wall motion abnormality; however, ESV did increase and reduced stroke volume. As percent abnormally contracting segments worsened, enlargement of both EDV and ESV was seen and was associated with further reduction in systolic volume.

These data suggest that EF is the best global left ventricular function correlate of the severity of the regional wall motion abnormality, and that abnormal motion in the territory of the left anterior descending coronary best predicts reduction in global left ventricular function. Radionuclide ventriculography is useful in characterizing global and regional left ventricular function in the early hours of acute myocardial infarction.

Impairment of left ventricular function in acute myocardial infarction has been directly related to the quantity of myocardium damaged.[1–6] The size of the acute infarct, as determined by enzymatic, electrocardiographic, and angiographic approaches, has been shown to correlate with ejection fraction (EF).[7,8] Furthermore, in patients with acute myocardial infarction, EF correlates well with clinical and hemodynamic evidence of heart failure.[9] Recent studies suggest that other parameters of global left ventricular function such as end-diastolic and end-systolic volumes may offer additional insights into left ventricular function, because the EF may be affected by factors other than contractility such as left ventricular afterload or preload, or both.[10–12] The left ventricular pressure/volume ratio at end-systole has been suggested as a valuable parameter for assessing global function because it appears to be relatively insensitive to cardiac loading and reflects changes in left ventricular contractility.[13] In addition, although the effect of location and type of asynergy on the ejection and nonejection phase indexes has been

pool images were recorded in both the anterior and 45° left anterior oblique projection which best defined the ventricular septum with an Anger scintillation camera (Ohio-Nuclear Series 420 mobile camera with 550 computer) equipped with an all-purpose, parallel-hole collimator. The pulse height analyzer was centered at 140 keV with a 20% window. The cardiac cycle was separated into ≥20 equal segments. A minimum of 200,000 counts were collected in each segment.

To calibrate the images for calculation of volume, a lead bar pattern of known dimensions was imaged at the conclusion of patient data collection. The number of picture elements between the bars on the image was determined and compared with the distance between the bars to complete the calibration process.

The data were translated and interpreted in a standardized fashion on a Medical Data System (MDS) A^2 computer. The data were reviewed and interpreted independently by at least 2 experienced observers, and the results were averaged.

Radionuclide data analysis: The left ventricular EF was calculated from the left anterior oblique view using a variable region of interest-counts method. Previous studies in our laboratory have revealed <5% intraobserver variance with this method.[17]

The end-diastolic volume (EDV) was calculated using a biplane area-length method.[18,19] Briefly, after calibration of picture element size, the end-diastolic outline of the ventricle was drawn by the viewer in both the anterior and left anterior oblique views, and then longest chords, areas, and minor axes were determined and corrected for nonorthoganality and rotation by computer and the end-diastolic volume was calculated. To validate the determination of EDV with the area-length method, the radionuclide EDV was correlated with that derived from direct contrast angiography in 44 other patients having both studies within 2 weeks,[20] with an overall correlation coefficient of $r = 0.84$. The stroke volume and end-systolic volume (ESV) were calculated from the EF and EDV. The peak systolic cuff pressure/end systolic volume ratio (PSP/ESV) was calculated from the cuff systolic pressure as has previously been reported.[19] Cardiac output was calculated as stroke volume times heart rate. Volumes were expressed as both absolute volume and corrected for body surface area.

To define regional wall motion, the left ventricular perimeter was divided into 5 segments on the anterior and left anterior oblique views (Fig. 1) as defined in the Coronary Artery Surgery Study Protocol.[21] A 5-point grading scale, ranging from 4 (normal) to 0 (dyskinesis), was assigned to each segment by 2 observers viewing an endless-loop movie of the multigated scan in both the anterior and left anterior oblique projections.[17] The score of each segment was summed to derive a wall motion index. Therefore, 40 (10×4) was the highest possible (normal) wall motion index score. Patients then were divided into 5 groups, ranging from near normal to severely impaired, based on their wall motion index: Group 1 = 36 to 40; Group 2 = 31 to 35; Group 3 = 26 to 30; Group 4 = 21 to 25; Group 5 ≤20. In addition, the percent abnormally contracting segments (that is, segments that were akinetic or dyskinetic—percent abnormally contracting segments) was calculated. The percent abnormally contracting segments was expressed in multiples of 10%, because the left ventricular perimeter was divided into 10 segments.

Statistical analysis: Mean differences among groups of patients were analyzed by means of a one-way analysis of variance and the Neuman-Keuls multiple comparison test. The correlation between parameters was assessed using linear regression analysis.[22] Differences of these correlations were assessed by Fisher's Z value. To determine which of these parameters of global left ventricular function correlated best

Global left ventricular function in relation to wall motion index. Results are expressed as the mean ± 1 standard deviation. Differences betwee groups were analyzed by 1-way analysis of variance and the Newman-Keuls multiple comparison test.

* $p < 0.05$.

† $p < 0.01$.

%ACS = the percentage of abnormally contracting segments; CI = cardiac index; EDVI = left ventricular end-diastolic volume index; EF = ejection fraction; ESVI = left ventricular end-systolic volume index; HR = heart rate; PSP = peak systolic blood pressure; PSP/ESV = peak systoli blood pressure/left ventricular end-systolic volume; SVI = stroke volume index.

with wall motion index and which segment score correlated with global left ventricular function, a stepwise multiple linear regression analysis was employed. In this analysis, each segment score was evaluated for its ability to explain the variation in global ventricular response. Those segments whose scores correlated best with global function were identified, and the analysis was repeated with exclusion of these data to identify the next most important segment, and so forth. Differences in the incidence of abnormal wall motion in each segment were assessed by the chi-square test. All mean values were expressed as mean ± 1 standard deviation.

The peak CPK value was compared with the EF at the time of admission by linear regression analysis.

Results

Relation of global left ventricular function and wall motion index (Table I): Increasingly severe wall motion abnormalities were associated with significant increases in heart rate and ESV, whereas EDV began to increase only after more severe damage to the myocardium (Groups IV and V). There were significant decreases in EF, stroke volume, cardiac index, and PSP/ESV with moderate reduction in wall motion (Group II). Peak systolic cuff pressure was not significantly different among the groups. Eleven patients had completely normal wall motion (index of 40) and their mean global function values were: EF 72 ± 10%; EDV 70 ± 11 ml/m^2; ESV 201 ± 11 ml/m^2; and PSP/ESV 5.(± 2.3 mm Hg/ml. These values do not differ signifi cantly from those of the Group I patients and did no differ from normal values previously reported from ou laboratory.[18,19]

The parameters of global left ventricular functio whose correlation coefficients reached statistical sig

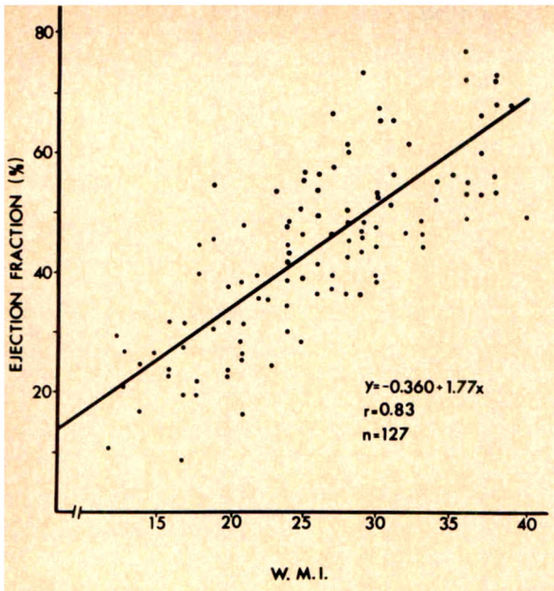
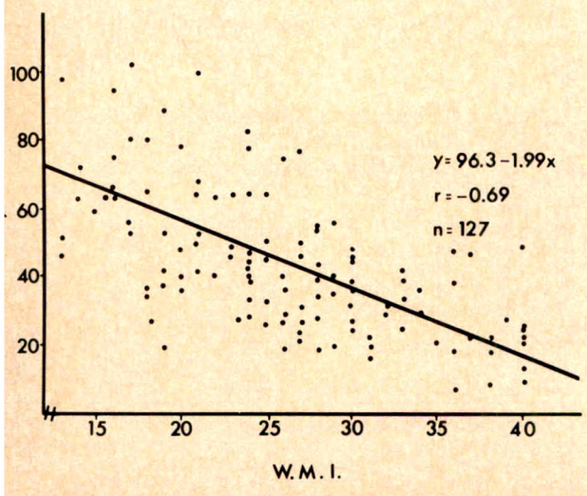
‡ $p < 0.01$.



URE 2. Relation of left ventricular ejection fraction to wall motion ex (W.M.I.). The line of best fit is plotted and the regression equation hown along with the correlation coefficient.

icance when compared with wall motion index are own in Table II. The correlation coefficient for EF th wall motion index was significantly larger than the lues for PSP/ESV and ESV with wall motion index. roke volume and cardiac index correlated less well th wall motion index and EDV correlated poorly with ll motion index. The individual plots for EF, ESV, d PSP/ESV in relation to wall motion index are own in Figures 2 to 4.

Stepwise multilinear regression of parameters of bal left ventricular function with wall motion index vealed that EF was the best correlate (F = 96.0, p .001), explaining 73% of the variance of regression:



URE 4. Relation of left ventricular end-systolic volume index (ESVI) wall motion index (W.M.I.).

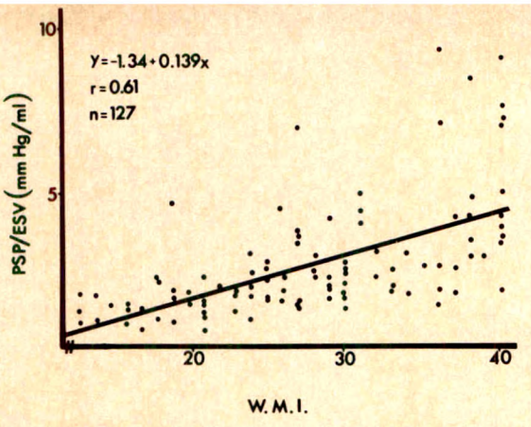


FIGURE 3. Relation of peak systolic blood pressure/left ventricular end-systolic volume (PSP/ESV) to wall motion index (W.M.I.).

wall motion index = 8.879 + 36.0 × EF. No other parameter added significantly to the regression.

Relation between EF and PSP/ESV: The relation between EF and PSP/ESV was curvilinear (Fig. 5). This basis relation was not altered when ESV was normalized by body surface area. When EF was related to the log of PSP/ESV, a significant linear correlation was found; log PSP/ESV = 0.458 (−0.0308 × EF) (r = 0.83, p <0.00005) (Fig. 6).

Influence of regional wall motion on global left ventricular function: The incidence of abnormal wall motion in each segment is shown in Table III. The apical and inferoapical segments were most frequently involved, whereas the anterobasal and superolateral segments were least frequently involved. All segments were involved in at least 30% of the patients. The anterobasal, superolateral, or inferobasal segments were not abnormal unless another segment was also involved. In 47 patients in which these 3 segments were normal, the percent abnormally contracting segments was sig-

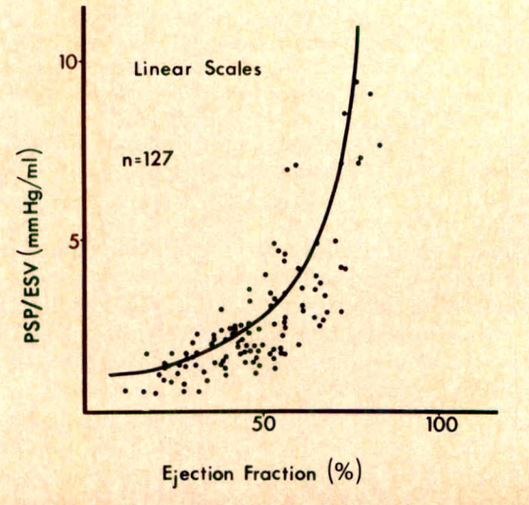

FIGURE 5. Relation between peak systolic blood pressure/left ventricular end-systolic volume (PSP/ESV) and ejection fraction.

nificantly smaller than in the 69 cases in which the aforementioned segments were abnormal (18 ± 16% and 29 ± 22%, p <0.005).

The correlations of EF, PSP/ ESV, and ESV with regional wall motion scores by multiple linear regression analysis are shown in Table IV. Motion in the apical-septal, anterobasal, inferoapical, anterolateral, and superolateral walls correlated best with EF; EF = −15.35 + 7.38 × (anterobasal) + 3.36 × (apical-septal) + 3.32 × (inferoapical) + 2.95 × (anterolateral) + 3.95 × (superolateral) where EF is in percent units. These segments also correlated best with both ESV and PSP/ESV.

The peak CPK values ranged from 76 to 2,050 IU and correlated poorly with EF (r = 0.17).

Discussion

Radionuclide method of assessing left ventricular function: Previous studies from several laboratories[23–26] have demonstrated that radionuclide techniques correlate closely with contrast ventriculography in measuring EF and regional wall motion. Recent work by Boucher et al[18] and Massie et al[27] shows that the determination of left ventricular EDV using the geometric method employed in this study correlates well with that derived from contrast angiography. In addition, Palacios et al[28] correlated left ventricular volume calculated from biplane gated scan using the area-length method with the true volume in human cadaver hearts and found a close correlation (r = 0.98). To minimize any potential problems with the assumed geometric ellipsoid model, the volume was calculated on the end-diastolic image only and ESV derived from EDV and EF.

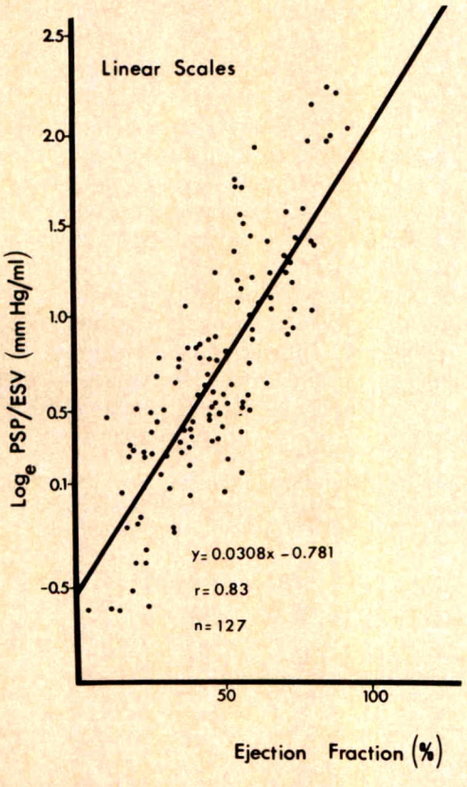

FIGURE 6. Relation between peak systolic blood pressure/end-systolic volume (PSP/ESV) and ejection fraction. The values in PSP/ESV were transformed into natural logarithmic number, and linear regression analysis between PSP/ESV and ejection fraction was performed.

TABLE III Frequency of Abnormal Wall Motion in Each Left Ventricular Segment (n = 127)

Anterior view		
Anterobasal	41	32%
Anterolateral	92	72%
Apical	108	85%

Basal-septal	89	70%
Apical-septal	95	75%
Inferoapical	107	84%
Posterolateral	82	65%
Superolateral	39	31%

The use of PSP/ESV as a noninvasive measure of contractility has been reported,[19,29,30] but makes the following assumptions: (1) the left ventricular end-systolic pressure-volume relation is linear; (2) the intercept of the line of end-systolic pressure volume relation does not change significantly with the early stage of acute myocardial infarction; (3) left ventricular end-systolic pressure can be approximated by the systolic pressure measured by the cuff method; and (4) left ventricular ESV may be assessed noninvasively.

Previous studies have correlated regional wall motion scores for the gated scan within ±1 grade with scores for contrast ventriculography in 84% of patients. This correlation was observed despite the fact that the inferobasal segment of the left ventricle may be difficult to define on the anterior view, and the wall motion analyzed for the septum differs in the 2 technologies. The best agreement occurred in the anterolateral surface (88%), and the worst agreement in the apex and septum (82%).[17,26,31] Although quantitative methods employing either a count-based or geometric analysis were avail-

ible for determination of regional wall motion, they were not employed in this study. Instead, the subjective method of interpretation using multiple independent readers as just described was used.

Relation of global left ventricular function to wall motion index: Ejection fraction, PSP/ESV, and ESV were abnormal even in patients (Group II) with relatively mild reduction in wall motion. The acute response to a small or moderate-sized myocardial infarction was an increase in ESV and a decrease in stroke volume without a significant change in EDV. Only in patients with severe impairment of wall motion did the EDV increase, as ESV increased in excess of the decrease in stroke volume. Our data are consistent with those of Klein et al[32] who found that the left ventricle only enlarges when 20 to 25% of the surface area is rendered akinetic.

Twenty-five patients (20%) had a small enough infarct that their wall motion was nearly normal (Group), and 11 (9%) had completely normal regional wall motion and global left ventricular function. The explanation for the lack of sensitivity of radionuclide ventriculography for a small infarct is unclear. The parameters measured in these patients may possibly have worsened compared with their preinfarct status, but were still in the normal range. It is less likely that an increase in contraction of the noninfarcted area may have occurred (because of increased sympathoadrenal discharge)[33,34] to maintain global function, because no abnormality in regional function was observed.

Although EF, ESV, and PSP/ESV correlated well with wall motion index, a stepwise multilinear regression analysis revealed that EF was the best single correlate and that no other variable added significantly to the regression. These data suggest that within hours of the acute injury, EF is the best indicator of overall wall motion in the early phase of acute myocardial infarction.

Previous studies have demonstrated that ESV increased when left ventricular contractility was reduced and when afterload was increased but was minimally affected by isolated changes in preload.[35–37] As a result, some suggest that ESV is a better indicator of intrinsic myocardial function than is the EF.[38] Although ESV did increase as wall motion worsened, this parameter did not correlate with wall motion as well as did EF. However, information about ventricular volumes and systolic blood pressure might be of additional value to EF for a more complete understanding of the changes in the functional state of the left ventricle.

The relation between PSP and ESV (PSP/ESV) is an attempt to make a noninvasive approximation of contractility (Emax), a parameter of left ventricular function that appears to be independent of preload which incorporates afterload.[39] A decrease in Emax has been found in patients with low EF.[12,40] Furthermore, previous studies suggested that it may be useful in detecting subtle abnormalities of left ventricular function in coronary disease.[29,30] However, our data suggest that in patients with acute myocardial infarction its value in addition to EF is less certain.

The nonlinear relation between PSP/ESV and EF (Fig. 5) is similar to that of Sagawa et al[13] concerning Emax and EF. The shape of the curve suggests an insensitivity of the normal EF to changes in Emax, whereas there is an insensitivity of the reduced Emax to changes in EF. This finding is not surprising because these parameters are derived from each other. The PSP/ESV was derived from PSP/(EDV × (1 − EF)). Because PSP was not significantly different between groups, the PSP/ESV ratio might be approximately expressed as constant/1 − EF.

Contribution of segmental wall motion to global function: Although Herman and Gorlin[14] and other investigators[41–43] have examined the relation of the location of Q wave to asynergy in left ventricular ventriculograms, postmortem infarct size, or coronary artery anatomy, or all 3, the relation of segmental wall motion to global ventricular function in the early phase of patients with myocardial infarction has not been examined in detail. In the present study the percent abnormally contracting segments of the walls usually perfused by the left anterior descending coronary artery (apical-septal, anterobasal, inferoapical, anterolateral and superolateral) correlated with EF. Although the anterobasal and superolateral walls were abnormal the least frequently, these segments appear to be involved in patients with larger infarctions.

Of interest, we found no correlation between peak creatine kinase and EF. One explanation is that a variable degree of ischemic dysfunction (reduced wall motion in noninfarcted areas) may have been present in our patients, a finding consistent with the observation that EF improves in some patients after infarction. In addition, the selection of patients for these studies eliminated those with extensive necrosis and cardiogenic shock, thereby limiting the range of comparisons between the 2 parameters. Alternatively, peak creatine kinase may not be an ideal measure of infarct size, and an integration of the area under the creatine kinase curve may be better. In either case, this lack of correlation does not alter the basic observations of the study regarding the relation of global to regional function in acute myocardial infarction; moreover, in the acute situation, in a patient with a first infarction, EF characterizes left ventricular function better than any other parameter.

Effect of Metoprolol on Indirect Signs of the Size And Severity of Acute Myocardial Infarction

JOHAN HERLITZ, MD, PhD, DAG ELMFELDT, MD, PhD, ÅKE HJALMARSON, MD, PhD, STIG HOLMBERG, MD, PhD, IVAN MÁLEK, MD, PhD, GUNNAR NYBERG, MD, PhD, LARS RYDÉN, MD, PhD, KARL SWEDBERG, MD, PhD, ANDERS VEDIN, MD, PhD, FINN WAAGSTEIN, MD, PhD, ANDERS WALDENSTRÖM, MD, PhD, JOHAN WALDENSTRÖM, MD, PhD, HANS WEDEL, PhD, LARS WILHELMSEN, MD, PhD, and CLAES WILHELMSSON, MD, PhD

In a double-blind randomized trial, 1,395 patients with suspected acute myocardial infarction (MI) were investigated to evaluate the possibility of limiting indirect signs of the size and severity of acute MI with the beta$_1$-selective adrenoceptor antagonist metoprolol. Metoprolol (15 mg) was given intravenously and followed by oral administration for 3 months (200 mg daily). Placebo was given in the same way. The size of the MI was estimated by heat-stable lactate dehydrogenase (LD[EC 1.1.1.27]) analyses and precordial electrocardiographic mapping. Lower maximal enzyme activities compared with placebo were seen in the metoprolol group (11.1 ± 0.5 μkat·liter^{-1}) when the patient was treated within 12 hours of the onset of pain (13.3 ± 0.6 μkat·liter^{-1}; n = 936; p = 0.009). When treatment was started later than 12 hours, no difference was found between the 2 groups. Enzyme analyses were performed in all but 20 patients (n = 1,375). Precordial mapping with 24 chest electrodes was performed in patients with anterior wall MI. The final total R-wave amplitude was higher and the final total Q-wave amplitude lower in the metoprolol group than in the placebo group. Patients treated with metoprolol ≤12 hours also showed a decreased need for furosemide, a shortened hospital stay, and a significantly reduced 1-year mortality compared with the placebo group, whereas no difference was observed among patients treated later on. After 3 months, however, there was a similar reduction in mortality among patients in whom therapy was started ≤12 hours and >12 hours after the onset of pain. The results support the hypothesis that intravenous metoprolol followed by oral treatment early in the course of suspected myocardial infarction can limit infarct size and improve long-term prognosis.

The conventional treatment of patients with acute myocardial infarction (MI) is directed mainly at complications such as pump failure and arrhythmias. An alternative approach is to attempt to influence the natural evolution of the impending MI by interrupting the process in its reversible phase, thereby limiting the final size of the MI.

The size of the MI greatly influences the short-term prognosis[1] and most likely also the long-term prognosis.[2] The hypothesis that beta blockade may limit MI development in man emanates from animal studies,[3–5] which were followed by several pilot investigations in man.[6–8] In most studies, results indicating MI limitation were obtained. However, the number of patients was mostly small and a placebo group was not always included. In a previous report, results regarding overall mortality in the metoprolol study were presented. A secondary objective of this trial was to investigate whether the beta$_1$-selective adrenoceptor antagonist metoprolol given intravenously and orally in the acute stage of suspected MI limits indirect signs of the size and severity of acute MI.

Methods

Between June 1976 and January 1981 all patients entering the 2 coronary care units in the city of Göteborg and that in the nearby community hospital in Skövde were assessed. Criteria for inclusion in the study were (1) residence in the recruitment area, (2) chest pain of acute onset and ≥30 minutes' duration or electrocardiographic signs of acute MI with estimated onset of MI within the previous 48 hours, (3) age between 40 and 74 years. The entry criteria were fulfilled by 2,619 patients, who were then evaluated with regard to possible exclusion (Table I). A detailed description of the study design and of the 3-month mortality was given previously.[9] After exclusion, 1,395 patients were randomly allocated to

TABLE I Selection of Patients for the Study

Selection	Number (%)
Patients eligible for the study	2,802
Patients included in other studies	183
Patients evaluated for entry	2,619
Patients excluded from entry because of contraindications	1,224 (47)*
Contraindications to beta blockade	353 (28)
Cardiovascular	311 (25)
Hypotension (<100 mm Hg)	63 (5)
Bradycardia (<45 beats/min)	21 (2)
Heart failure (basal rales <10 cm, poor peripheral circulation, shock)	183 (15)
Atrioventricular block	44 (3)
Bronchial asthma	42 (3)
In need of beta blockade	257 (21)
Serious or multiple diseases	92 (8)
Administrative reasons	510 (42)
Refusal to participate	131 (11)
Psychiatric disease, alcoholism	126 (10)
Chronic atrial fibrillation	67 (5)
Pacemaker at entry	43 (4)
Nonresident or language problems	43 (4)
Planned or previous coronary bypass	38 (3)
Minor noncardiovascular adverse reactions to beta-blockade	27 (2)
Confused or unconscious	20 (2)
On "CA^{++} antagonists" at entry	15 (1)
Reason missing	12 (1)
Randomized to blind treatment	1,395 (53)*

* The percentage of 2,619 patients is given for the number of patients excluded because of contraindications and those randomized, respectively. All other figures in parentheses represent the percentage of patients who were excluded from entry.

TABLE II Patient Profile: Comparison of Placebo and Metoprolol Groups

Characteristics	Placebo Group (n = 697) (%)	Metoprolol Group (n = 698) (%)
Sex		
Men	76.2	75.5
Women	23.8	24.4
Age (yr)		
<64	65.0	66.5
65–74	35.0	33.5
Clinical history		
Previous infarction	22.7	21.2
Angina pectoris (5)*	34.7	35.7
Hypertension	29.7	29.1
Therapy before admission		
Digitalis (6)	12.9	12.5
Diuretics (5)	18.7	18.7
Beta-blocking drugs	25.4	25.2
Clinical status at entry		
Pulmonary rales	9.0	11.6
ECG signs of infarction (1)	47.8	49.9
Heart-rate >100 beats/min (1)	6.2	4.7
Systolic blood-pressure <110 mm Hg (2)	4.4	3.3
Dyspnea at onset of pain (29)	30.8	28.8
Treatment in hospital before blind injection		
Morphine (3)	53.9	53.6
Atropine (3)	3.5	2.9
Isoprenaline or analogues (2)	0.0	0.0
Diuretics (3)	9.8	10.8
Digitalis (3)	1.9	2.3
Lidocaine (3)	2.7	2.3
Beta-blocking drug or verapamil (5)	1.6	2.2
Mean age ± SEM	60.0 ± 0.3	60.0 ± 0.3
Mean time from onset of symptoms to blind injection ± SEM (16)	11.4 ± 0.4	11.1 ± 0.4

* Numbers of missing data are given in parentheses.
SEM = standard error of the mean.

double-blind treatment; 698 received metoprolol and 697 placebo. Patient characteristics are given in Table II.

Treatment was started as soon as possible after arrival in the hospital. Metoprolol was given in a dose of 15 mg intravenously (5 mg at a time with 2-minute intervals between injections) followed by 50 mg orally every 6 hours (first tablet 15 minutes after last injection) for 48 hours and then 100 mg twice a day for 3 months. Placebo was given in the same way. After 3 months, patients with ischemic heart disease and no contraindications were treated with metoprolol 100 mg twice daily for at least 2 years. The distribution of patients in relation to the time interval between onset of pain and blind injection is given in Figure 1. In patients included in the study developing a systolic blood pressure <90 mm Hg, heart rate <40 beats/min, atrioventricular block (P-Q ≥0.26 second), or severe heart failure, the dose was usually halved. If no improvement occurred, the blind medicine had to be withdrawn (Table III).

Blood samples for heat-stable lactate dehydrogenase (LD [EC 1.1.1.27] earlier referred to as LD I + II[9]) analysis were taken every 12 hours for 48 hours in 466 patients, for 60 to 84 hours in 191 patients, and for 96 to 108 hours in 718 patients. Heat-stable LD values were thus obtained in all but 20 patients (n = 1,375). In the remaining 20 patients either samples were lost or it was impossible to obtain blood from the patient because of poor clinical condition, early death, or unwillingness. The highest enzyme value obtained in each patient was used as a measure of the infarct size. To correlate this enzyme with a more widely used enzyme, creatine kinase (CK [EC 2.7.3.2]) and also CK B was analyzed every 6 hours for 48 hours in a subgroup. The heat-labile isoenzymes of LD were inactivated according to the method described by Brydon and Smith.[10] LD, aspartate amino transferase (ASAT), and alanine amino transferase (ALAT) were determined according

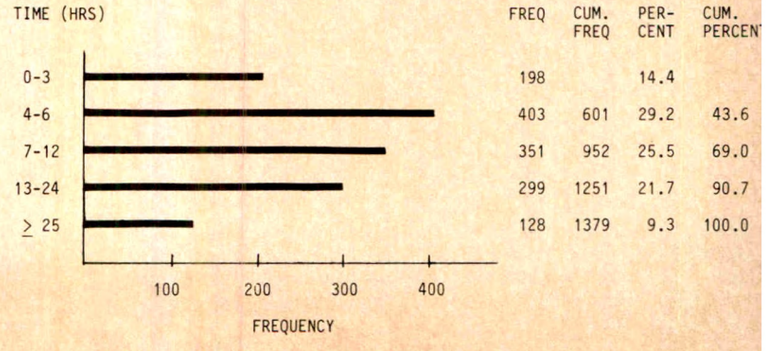

FIGURE 1. Number and percentage of patients given blind injections within different time intervals after onset of pain. Missing data in 16 patients. CUM. = cumulative; FREQ = frequency.

Cardiovascular Reasons During the Initial Hospital Stay

Reasons for Withdrawal	Patients Withdrawn: Placebo Group (696) n	Placebo Group (696) %	Metoprolol Group (696) n	Metoprolol Group (696) %	Significance (2p)
Hypotension	10	1.4	26	3.7	0.010
Bradycardia	5	0.7	16	2.3	0.026
Atrioventricular block II or III	10	1.4	15	2.2	>0.2
Heart failure	3	0.4	3	0.4	...
Need for beta-blockade	13	1.9	6	0.9	0.160
Total	41	5.9	66	9.5	0.012

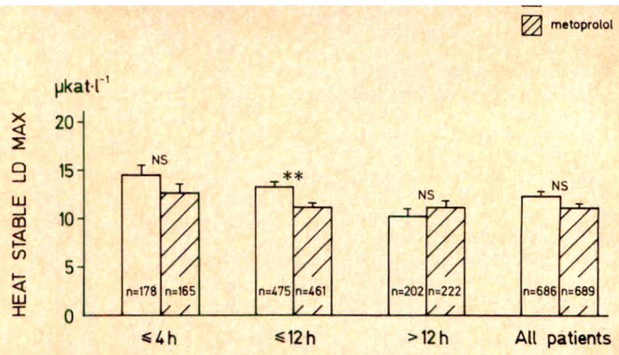

FIGURE 2. Mean maximal (MAX) heat-stable lactate dehydrogenase (LD) activities in all patients and those given blind injection within different time intervals after the onset of pain. Missing data in 15 of the patients in whom enzyme values were obtained. ** $p < 0.01$.

to the method recommended by the Scandinavian Committee on Enzymes.[11] CK was determined according to a modified method recommended by the Scandinavian Committee on Enzymes.[12]

CK B was determined with an immune inhibition method according to Gerhardt and Waldenström.[13] The area under the enzyme curve was calculated according to Davis and Rabinowitz.[14] One enzyme unit catal is defined as the enzyme activity that transforms 1 mole of substrate per second.

Precordial mapping with 24 chest electrodes arranged in 6 vertical rows (the first 2 rows symmetrically on both sides of the sternum) was performed before the blind injection and 4 days later. The Q and R wave amplitude was analyzed in patients with anterior MI (changes in leads V_1 to V_5 in standard electrocardiogram). A pathologic Q wave was defined as >0.03 second wide and >1 mm deep or ≥0.03 second wide with a Q/R ratio ≥0.33 and >1 mm deep. The paper speed was 50 mm/s. Amplification was standardized, that is, 10 mm = 1 mV.

A QRS duration >0.10 second or axis deviation beyond −30° and +120° in the frontal plane was not accepted. The P-Q segment was used as the isoelectric line. Mapping was performed at end-expiration and reclining at 30°. At each electrocardiographic position the Q and R waves were measured to the nearest 1.0 mm. The total R-wave amplitude (ΣR) and total Q-wave amplitude (ΣQ) in the 24 electrodes were calculated on the fourth day.

The following criteria were used for classification of definite and probable MI. For definite MI 2 of the following 3 criteria had to be fulfilled: (1) chest pain of at least 15 minutes' duration, (2) Q-wave or S-T segment elevation followed by T-wave inversion in at least 2 electrodes in a 12-lead standard electrocardiogram, and (3) 2 serum ASAT values above the normal value in combination with lower or normal serum ALAT values. Electrocardiographic changes in only 1 electrode or only 1 elevated ASAT value in combination with at least 1 heat-stable LD value above a discriminatory level were also regarded as definite MI. For probable MI, chest pain plus 1 of the following criteria was required: (1) T-wave inversions, (2) 1 elevated ASAT value in combination with lower or normal ALAT values, (3) 1 or more elevated heat-stable LD values, or (4) Q-wave or S-T segment elevation followed by T-wave inversion in only 1 electrode.

Late infarction was defined according to chest pain, ASAT, and electrocardiographic changes (in the same manner as previously described) or autopsy findings of an actual infarction that could be separated from a suspected initial infarction. The start of new symptoms related to the infarction must occur >3 days after inclusion in the study. Blood samples for heat-stable LD were not analyzed in these cases.

The total dose of furosemide given during the first 4 days in the hospital was calculated in 79% of the patients. The re-

FIGURE 3. Missing data in 9 patients in whom enzyme values were obtained. * $p < 0.05$.

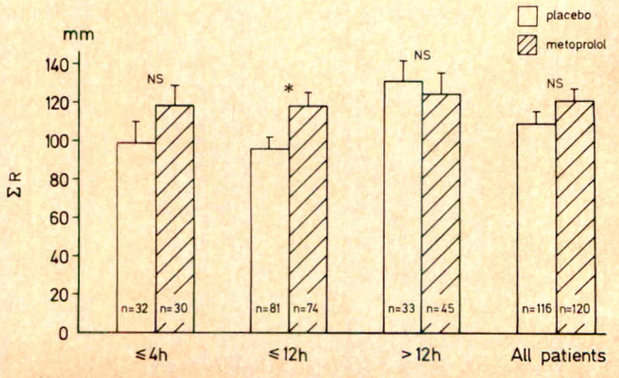

FIGURE 4. The sum of all R waves in the 24 precordial positions on the fourth day in anterior myocardial infarction (MI). * $p < 0.05$.

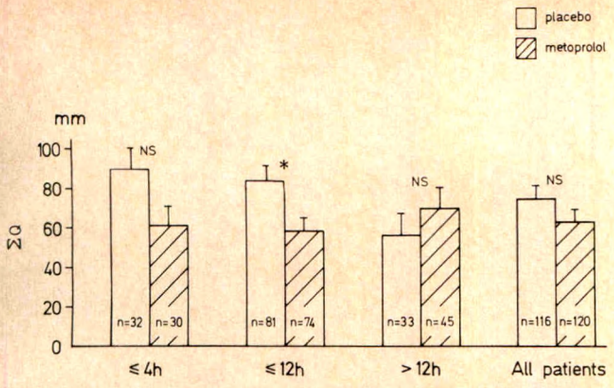

FIGURE 5. Sum of all Q waves in the 24 precordial positions on the fourth day of anterior myocardial infarction (MI). * p <0.05.

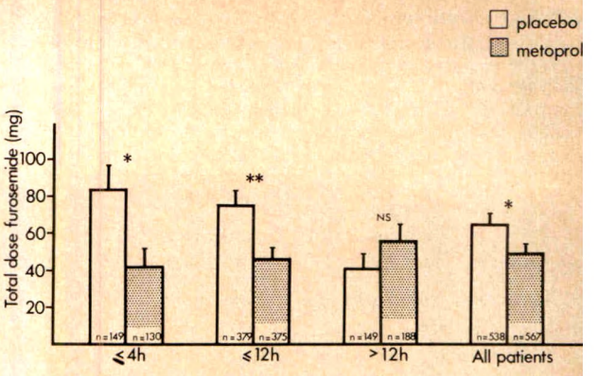

FIGURE 6. The total dose of furosemide given during the first 4 da in hospital. * p <0.05; ** p <0.01.

maining 21% in whom data were not collected included (1) patients on chronic furosemide before inclusion receiving furosemide after inclusion, and (2) patients receiving additional diuretics other than spironolactone. In a subgroup analysis regarding time from the onset of pain to the start of treatment, 4 and 12 hours were used as time limits. The reason was that in previous reports, which will be referred to, these time limits were used. All analyses presented are in accordance with the "intention to treat" concept.

Statistical methods: Fisher's permutation test was used.[15] A 2-tailed test was applied and a p value <0.05 was considered significant. Results are expressed as mean values ± standard error of the mean (SEM).

Results

Enzymes: *All patients* (*Fig. 2*): When all randomized patients were included, slightly lower activity (borderline significance) was found in the metoprolol group (11.1 ± 0.4 μkat·liter^{-1}) compared with the placebo group (12.4 ± 0.5 μkat·liter^{-1}; n = 1,375; p = 0.054). A highly significant difference in the total series was found in the patients treated within 12 hours of onset of pain (metoprolol 11.1 ± 0.5 μkat·liter^{-1}; placebo 13.3 ± 0.6 μkat·liter^{-1}; n = 936; p = 0.009). If treatment was started later than 12 hours after onset of pain, no difference between treated and untreated patients was observed. The disappearance rate of heat-stable LD was similar in the 2 groups. Altogether, a definite infarction developed in 399 patients during the first 3 days in the metoprolol group compared with 410 patients in the placebo group (difference not significant [NS]). Among patients included after ≤12 hours, the number of patients in respective groups in whom an infarction developed were as follows: metoprolol, 256 of 468 (55%); placebo, 294 of 484 (61%); p = 0.068. In patients in whom treatment was started >12 hours after the onset of pain, opposite trends were found: metoprolol, 140 of 224 (63%); placebo, 111 of 203 (55%); p = 0.123. Data regarding delay time were missing in 8 of the patients in whom MI developed, 3 in the metoprolol group and 5 in the placebo group.

Patients with definite or probable MI (*Fig. 3*): When all patients were analyzed, lower enzyme activity was seen in the metoprolol group (14.8 ± 0.5 μkat·liter^{-1}) than in the placebo group (16.5 ± 0.6 μkat·liter^{-1}; n = 954; p = 0.043). The effect was again restricted to p tients injected within 12 hours (metoprolol, 15.2 ± 0 μkat·liter^{-1}; placebo, 17.4 ± 0.8 μkat·liter^{-1}; p = 0.03 no difference was found among those in whom trea ment was started later.

Electrocardiography (anterior MI): A higher Σ was obtained in patients treated with metoprolol (117 ± 7.6 mm) within 12 hours than in the placebo grou (93.3 ± 6.4 mm; n = 155; p = 0.031), whereas no effe could be demonstrated among those treated later (Fi 4). Similar results were obtained for ΣQ (Fig. 5), a low ΣQ being obtained in the metoprolol group treate within 12 hours (metoprolol, 58.4 ± 7.0 mm; placeb 84.5 ± 7.6 mm; n = 155; p = 0.012), whereas no diffe ence was observed in the remaining patients.

Clinical findings: Tablet treatment was withdraw in 10% in the metoprolol group compared with 6% in t placebo group during the initial hospital stay for t reasons listed in Table III. More patients in the m toprolol group withdrew because of hypotension a bradycardia.

In the metoprolol group (n = 698), 4 patients had be treated with a beta-agonist (prenalterol) because severe reduction of systolic blood pressure in relati to the intravenous dose, compared with 1 patient in t placebo group. In these 4 patients there was a rap restoration of blood pressure after prenalterol trea ment. In 79% of all randomized patients the total do of furosemide given during the first 4 days in the ho pital was calculated. As seen in Figure 6, more fur semide had to be given to placebo patients than to m toprolol patients when treatment was started within hours (metoprolol, 46 ± 6 mg; placebo, 75 ± 8 mg; n 754; p = 0.003), whereas no difference was observed patients treated later.

Table IV compares the 2 groups regarding the dur tion of initial hospitalization in relation to the del from the onset of pain. The metoprolol-treated patien were hospitalized for a significantly shorter period th placebo patients if they received injection ≤4 and ≤ hours after the onset of pain, whereas no difference w observed among patients included later on.

Late infarction: Late nonfatal or fatal MI (onset MI on the fourth day after inclusion in the study later) occurred in 35 patients in the metoprolol grou

Randomly Allocated to Placebo or Metoprolol

Delay (Hours) From Onset of Pain to Blind Injection	Mean Hospital Days (n) ± SEM		Significance (2p)
	Placebo Group	Metoprolol Group	
≤4	11.8 ± 0.5 (172)*	10.3 ± 0.4 (158)	0.036
≤12	11.3 ± 0.4 (451)	10.1 ± 0.3 (442)	0.010
>12	10.5 ± 0.3 (192)	10.9 ± 0.5 (215)	>0.2
All patients	11.0 ± 0.3 (653)	10.3 ± 0.3 (663)	0.073

* Numbers in parentheses refer to number of patients.

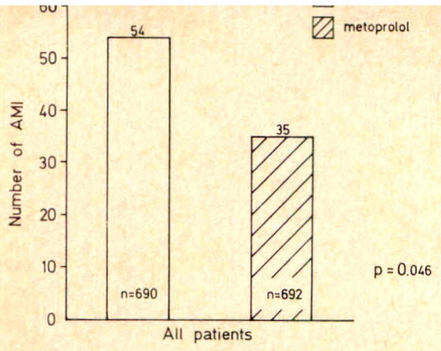

FIGURE 7. Number of patients who developed AMI from day 4 to 90 after inclusion. AMI = acute myocardial infarction.

nd 54 in the placebo group during the 3-month fol-ow-up (p = 0.046) (Fig. 7). Nonfatal late MI occurred n 27 patients in the metoprolol group versus 41 patients n the placebo group (NS). Of the 35 patients in whom late MI developed among those who received me-oprolol, 31 patients had a reinfarction (late MI after an nitial MI), whereas 48 of the 54 patients in the placebo roup were considered to have a reinfarction (NS). Among patients in whom treatment started ≤12 hours fter the onset of pain, late MI developed in 25 me-oprolol-treated patients versus 35 placebo-treated atients. In those in whom treatment was started >12 ours, the number of patients in whom late MI devel-ped was 10 versus 15 in respective groups. Data re-arding the time from onset of pain to the start of reatment were missing in the remaining 4 placebo-reated patients.

Infarct size and 3-month and 1-year survival, espectively (Table V): A similar reduction in 3-nonth mortality was found in patients in whom treat-nent was started within and after 12 hours of the onset f pain. A limitation of indirect signs of the infarct size ould be demonstrated only in patients treated early. When separately analyzing mortality from after 3 nonths to 1 year, during which time all patients re-eived the same treatment, 16 patients originally ran-omized to metoprolol versus 23 patients originally andomized to placebo died in the group treated within 2 hours, whereas 8 metoprolol versus 6 placebo patients ied in the group treated later. There was a significant eduction in the total 1-year mortality rate among pa-tients treated with metoprolol within 12 hours compared with the placebo group, whereas no difference was observed between the 2 groups among patients treated later on.

Correlations: A highly significant correlation among all patients with definite MI was found between peak heat-stable LD and peak CK (r = 0.84; n = 216; p <0.001) (Fig. 8) as well as peak CK B (r = 0.81; n = 204; p <0.001).

A highly significant, although weaker correlation was also found between peak heat-stable LD and ΣR on the fourth day in anterior MI (r = 0.56; n = 179; p <0.001) and ΣQ on the fourth day in anterior MI (r = 0.62; n = 179; p <0.001). There was a high correlation between the peak heat-stable LD value and the area under the 48-hour enzyme curve (r = 0.94; n = 594; p <0.001) and the area under the 108-hour enzyme curve (r = 0.98; n = 450; p <0.001), respectively.

Discussion

In this study 2 independent methods were used to evaluate possible limitation of the infarct size. In awareness of the uncertainty of the 2 methods,[16,17] a comparison between them was made and a significant positive correlation found. Therefore, it was not surprising that the 2 methods gave similar information when the effect of metoprolol on indirect signs of ne-

ABLE V Effect of Early and Late Intervention in Various Subgroups Randomly Allocated to Placebo or Metoprolol

	Delay (Hours) From Onset of Pain to Blind Injection

Missing data regarding time intervals in 2 dead patients (placebo); 1 patient died within 3 months and 1 patient died between 3 and 12 months.
LD = lactate dehydrogenase.

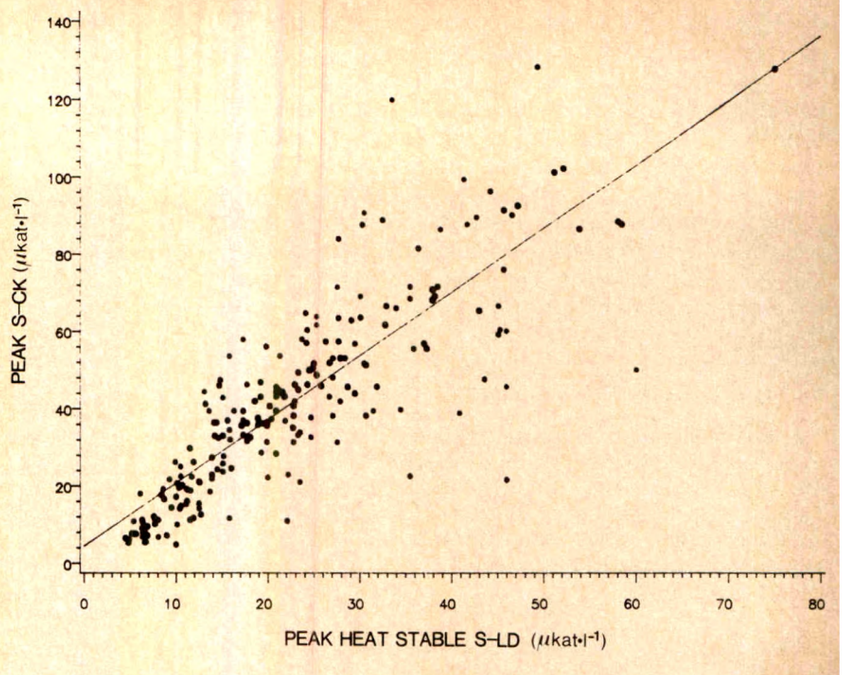

FIGURE 8. Correlation between the peak value of heat-stable serum lactate dehydrogenase (S-LD) and serum creatine kinase (S-CK). n = 216; r = 0.84; p <0.001.

crosis was evaluated. The results are in accordance with those of previous reports.[18,19]

From experience in animal experiments, more pronounced effects could have been expected in patients treated within 4 hours. In a previous report[20] with few patients, results favoring this idea were presented. We found similar results in patients treated within 12 hours compared with those treated within 4 hours. One explanation for this finding might be that patients arriving in the hospital very early have low-flow ischemia in a higher proportion (sudden total coronary obstruction), whereas patients arriving somewhat later have a higher proportion of moderate or high-flow ischemia more apt to receive intervention. Thus, although early intervention is of major importance, other factors might influence the choice of patients suitable for intervention in MI.

It has been argued that beta blockade may increase enzyme clearance and thereby cause lower serum enzyme activity in acute MI.[21] Studies in man do not support this hypothesis.[20] The disappearance rate of heat-stable LD was also similar in the metoprolol group compared with the placebo group in the present study. The possibility that beta blockade may decrease myocardial perfusion and thereby increase local inactivation of enzymes has also been discussed.[20] However, the fact that in this study, as in earlier investigations,[19,20] no effect on enzyme activities was found when the drug was given late speaks against this explanation, as does the observation of metoprolol-induced limitation of Q- and R-wave changes. To determine whether plasma volume was different in treated and nontreated patients, we determined the alpha$_2$-macroglobulin concentration in serum in a small subsample. Treated patients had a similar mean concentration 36 hours after inclusion compared with patients receiving placebo, indicating that metoprolol does not influence the intravasal distribution volume.

It is possible that beta blockade influences the Q and R waves by nonspecific mechanisms not related to the ischemic damage. However, it does seem unlikely that an increase in end-diastolic volume, for example, would result in an increase in the R-wave amplitude and a simultaneous decrease in Q-wave amplitude.

Heart failure was estimated by calculating the dose of furosemide given during the first 4 days. Furosemide is the main diuretic drug used in Sweden for heart failure in patients with MI. The results obtained gave similar information as the enzymes and the electrocardiographic data, namely, a beneficial effect of metoprolol if treatment was started within 12 hours, but not later. Whether or not beta blockade decreases the metabolism of furosemide may be questioned, but if so, why only in patients treated early. Also, beta blockade apparently did not induce cardiac decompensation.

Although no significant reduction was noted in the number of patients in the metoprolol group in whom MI developed during the first 3 days compared with the placebo group, there was a marked reduction in the number of late MI in the metoprolol-treated patients. Although limiting the final size of the infarction with beta blockade seems possible, the intervention probably generally starts too late to prevent the development of MI. Under any circumstances, if the patient is receiving chronic treatment with beta blockade, the drug might protect against new MI, as shown also in the Norwegian timolol trial.[22]

Within 3 months a similar reduction in mortality after treatment with metoprolol was achieved in patients treated early compared with those treated late. A significantly lower 1 year mortality was observed in the metoprolol group included within 12 hours, whereas

on. However, it must be emphasized that the decrease in 1 year mortality might depend to some extent on postinfarct effects of beta blockade during the first 3 months and also that the total number of deaths in the group for which treatment was started after >12 hours was quite small.

Treatment with metoprolol in the acute stage of MI was generally well tolerated. Complications were few and were easily discovered and handled. No difference was seen in the number of patients who had to stop treatment because of heart failure or atrioventricular block, whereas more metoprolol-treated patients withdrew because of hypotension or bradycardia.

Acknowledgment: This investigation was supported by grants from the Swedish Medical Research Council (projects B80-19X-2529-11A and B81-19X-2529-12B), the Swedish National Association against Heart and Chest Diseases, the Göteborg Medical Society, and AB Hässle, Mölndal, subsidiary of AB Astra, Södertälje, Sweden.

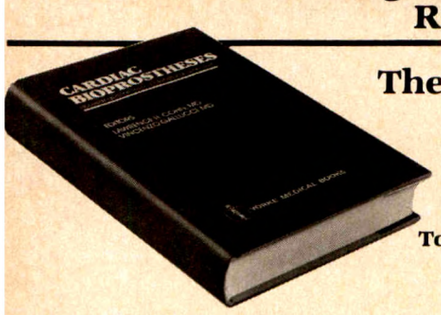
Proceedings of the Second International Symposium
Rome, Italy, May 17-19, 1982



The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

To order your copy of this important new book use the order form below.

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today.*

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology,* now available in its second issue, *Cardiology 1982.*

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

Table of Contents

Section 1 CLINICAL ANALYSIS 1. The Evolution of the Biological Valve **2.** Heart Valve Replacement with the Hancock Bioprosthesis: A 5-11 Year Follow-up **3.** A 14-Year Experience with Valvular Bioprostheses: Valve Survival and Patient Survival **4.** A Thousand Porcine Bioprostheses Revisited. Do They Conform with the Expected Pattern? **5.** Clinical Durability of the Pericardial Xenograft Valve: 11 Years' Experience **6.** Long-term Results of 159 Porcine Valve Implantations **7.** Mid- and Long-term Evaluation of Porcine Bioprosthetic Valves: A 6-Year Experience

Section 2 HEMODYNAMICS 8. Hemodynamic Evaluation of the Hancock Bioprosthesis in the Mitral Position: A 1-7 Year Follow-up **9.** Hemodynamic Evaluation of the Carpentier-Edwards Standard and Improved Anulus Bioprostheses **10.** Hemodynamic Evaluation in Valvular Patients Carrying Low Profile Bioprostheses **11.** Noninvasive Scintigraphic Assessment of Left and Right Ventricular Function in Patients with Bioprosthetic Mitral Valves at Long-term Risk **12.** Orifice View Roentgenography for Evaluation of the Orifice Area of Bioprosthetic Valves

Section 3 THROMBOEMBOLISM 13. Alterations in Valvular Surgery: Biological Valves **14.** Early and Late Results of Porcine Bioprostheses Versus Mechanical Prostheses in Aortic and Mitral Positions **15.** Mitral Bioprostheses in 202 Patients with Chronic Atrial Fibrillation, Giant Left Atrium, and Atrial Thrombi: Long-term Results with No Anticoagulation **16.** Thromboembolism and Anticoagulation after Isolated Mitral Valve Replacement with Porcine Heterografts **17.** Preoperative Determinants of Return to Sinus Rhythm after Valve Replacement **18.** Porcine Bioprostheses Versus Mechanical Valvular Substitutes: A Retrospective Comparative Analysis

Section 4 PEDIATRIC VALVE REPLACEMENT 19. Valved Conduits: A Panacea for Complex Congenital Heart Defects? **20.** Factors Influencing Late Results of Extracardiac Conduit Repair for Congenital Cardiac Defects **21.** Calcification of Porcine Bioprostheses in Children **22.** Valve Replacement in Children: Biological Versus Mechanical Valves **23.** Bioprosthetic Valve Replacement in Children **24.** Aortic Root Replacement **25.** Conduits Containing Antibiotic Preserved Homografts in the Treatment Of Complex Congenital Heart Defects **26.** Dura Mater Bioprosthesis in Young Patients

Section 5 EXPERIMENTAL PATHOLOGY 27. Experimental Evaluation of Bioprosthetic Valves Implanted in Sheep **28.** Role of Mechanical Stress in Calcification of Bioprostheses **29.** Inhibition of Mineralization of Glutaraldehyde-fixed Hancock Bioprosthetic Heart Valves **30.** Prevention of Tissue Valve Calcification by Chemical Techniques

Section 6 EXPLANT PATHOLOGY 31. Complications of Replacement of either the Mitral or Aortic Valve or Both by either Mechanical or Bioprosthetic Valves **32.** Pathogenesis and Stages of Bioprosthetic Infection **33.** Structure and Classification of Cuspal Tears and Perforations in Porcine Bioprosthetic Cardiac Valves Implanted in Patients **34.** Pathological Substrates of Porcine Valve Dysfunction **35.** Mode of Failure in 226 Explanted Biological and Bioprosthetic Valves

Section 7 BIOPROSTHETIC BIOENGINEERING 36. The Unileaflet Heart Valve Bioprosthesis **37.** Hancock II - An Improved Bioprosthesis **38.** Design and Stress Analysis of Bioprosthetic Valves In Vivo **39.** In Vitro Comparison of the Newer Heart Valve Bioprostheses in the Mitral and Aortic Positions **40.** In Vitro and In Vivo Assessment of the Flow Characteristics of the Xenomedica Porcine Xenograft **41.** The Structure/Function Relationship of Fresh and Glutaralhyde-Fixed Aortic Valve Leaflets

Section 8 LONG-TERM FOLLOW-UP 42. Bioprostheses in the Tricuspid Position Versus Valvuloplasty and Mechanical Valves **43.** The Role of Porcine Heterografts in a 14-Year Experience with Tricuspid Valve Replacement **44.** Patient Prosthesis Mismatch in the Tricuspid Position: The Rationale for an Oval Pericardial Tricuspid Valve **45.** The Porcine Bioprosthesis: Failure Rates in the Elderly **46.** Causes of Valve Failure and Indications for Reoperation After Bioprosthetic Cardiac Valve Replacement **47.** Clinical Analysis of the Hancock Porcine Bioprosthesis **48.** Valve Replacement in the Small Anulus Aorta: Performance of the Hancock Modified-Orifice Bioprosthesis **49.** Decreasing Incidence of Porcine Bioprosthetic Degeneration

Section 9 SUMMING UP 50. A Cardiologist's Point of View and a Cardiac Surgeon's Point of View

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

ten by 130 selected authorities, MYOCARDIAL
/ASCULARIZATION represents the first comprehensive
erage of the subject, presenting many new therapeutic
lalities not previously published anywhere. This volume is an
rowth of the recent International Symposium on Myocardial
ascularization held in Nassau, The Bahamas. It is edited by
internationally renowned specialists, Dean T. Mason, MD,
John J. Collins, Jr., MD.

EDITED BY

DEAN T. MASON, M.D.
Professor of Medicine and Physiology
Chief, Cardiovascular Medicine
University of California at Davis
School of Medicine and University Medical Center
Davis and Sacramento, California
Editor-In-Chief, AMERICAN HEART JOURNAL

JOHN J. COLLINS, JR., M.D.

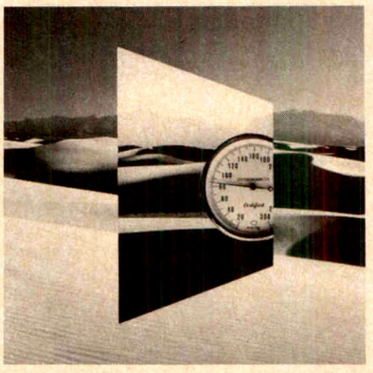
management of hypertension



No electrolyte or metabolic risk factors
No long-term cardiovascular risk factors
No immunologic disturbances
No liver damage
No contraindications except hypersensitivity

Side effects are usually mild and transient

Patients may experience drowsiness and dry mouth early during WYTENSIN® (guanabenz acetate) therapy, but these subjective complaints are mostly mild and transient, especially when the initial dosage is *4 mg b.i.d.*, with the second dose at bedtime.

WyTensin®
(guanabenz acetate)

4mg b.i.d.

f Summary

ons:
ensin® (guanabenz acetate) is an orally active
tral alpha-2 adrenergic agonist. Its antihyperten-
action appears to be mediated via stimulation of
tral alpha adrenergic receptors, resulting in a de-
se of sympathetic outflow from the brain at the
ar level to the peripheral circulatory system.
acute antihypertensive effect of **Wytensin** oc-
without major changes in peripheral resistance,
its chronic effect appears to be a decrease in pe-
eral resistance.

ications and Usage:
tment of hypertension, alone or in combination
a thiazide diuretic.

traindication:
wn sensitivity to the drug.

:autions:
dation: Causes sedation or drowsiness in a large
ion of patients. When used with centrally active
essants, e.g., phenothiazines, barbiturates and
todiazepines, consider potential for additive
tive effects.

itients with vascular insufficiency: Like other an-
pertensives use with caution in severe coronary
fficiency, recent myocardial infarction, cerebro-
ular disease, or severe hepatic or renal failure.

ebound: Sudden cessation of therapy with cen-
alpha agonists like **Wytensin** may rarely result
overshoot" hypertension and more commonly
luces increase in serum catecholamines and sub-
ve symptomatology.

ORMATION FOR PATIENTS:
ise patients on **Wytensin** to exercise caution
n operating dangerous machinery or motor ve-
es until it is determined they do not become
sy or dizzy. Warn patients that tolerance for al-
ol and other CNS depressants may be dimin-
d. Advise patients not to discontinue therapy
ptly.

TESTS:
linical trials, no clinically significant lab test ab-
nalities were identified during acute or chronic
apy. Tests included CBC, urinalysis, electrolytes,
T, bilirubin, alkaline phosphatase, uric acid,
, creatinine, glucose, calcium, phosphorus, total
ein, and Coombs' test. During long-term use
e was small decrease in serum cholesterol and total triglycerides without change in high-density lipoprotein fraction. In rare instances occasional nonprogressive increase in liver enzymes was observed, but no clinical evidence of hepatic disease.

DRUG INTERACTIONS:
Wytensin® was not demonstrated to cause drug interactions when given with other drugs, e.g., digitalis, diuretics, analgesics, anxiolytics, and antiinflammatory or antiinfective agents, in clinical trials. However, potential for increased sedation when given concomitantly with CNS depressants should be noted.

DRUG/LAB TEST INTERACTIONS:
No lab test abnormalities were identified with **Wytensin** use.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY:
No evidence of carcinogenic potential emerged in rats during a two-year oral study with **Wytensin** at up to 9.5 mg/kg/day, i.e., about 10 times maximum recommended human dose. In the Salmonella microsome mutagenicity (Ames) test system, **Wytensin** at 200-500 mcg per plate or at 30-50 mcg/ml in suspension gave dose-related increases in number of mutants in one (TA 1537) of five *Salmonella typhimurium* strains with or without inclusion of rat liver microsomes. No mutagenic activity was seen at doses up to those which inhibit growth in the eukaryotic microorganism, *Schizosaccharomyces pombe*, or in Chinese hamster ovary cells at doses up to those lethal to the cells in culture. In another eukaryotic system, *Saccharomyces cerevisiae*, **Wytensin** produced no activity in an assay measuring induction of repairable DNA damage. Reproductive studies showed a decreased pregnancy rate in rats given high oral doses (9.6 mg/kg), suggesting impairment of fertility. Fertility of treated males (9.6 mg/kg) may also have been affected, as suggested by decreased pregnancy rate of mates, even though females received drug only during last third of pregnancy.

PREGNANCY:
Pregnancy Category C:
WYTENSIN® MAY HAVE ADVERSE EFFECTS ON FETUS WHEN ADMINISTERED TO PREGNANT WOMEN. A teratology study in mice indicated possible increase in skeletal abnormalities when **Wytensin** is given orally at doses 3 to 6 times maximum recommended human dose of 1.0 mg/kg. These abnormalities, principally costal and vertebral, were not noted in similar studies in rats and rabbits. However, increased fetal loss has been observed after oral **Wytensin** given to pregnant rats (14 mg/kg) and rabbits (20 mg/kg). Reproductive studies in rats have shown slightly decreased live-birth-indices, decreased fetal survival rate, and decreased pup body weight at oral doses of 6.4 and 9.6 mg/kg. There are no adequate, well-controlled studies in pregnant women. **Wytensin®** should be used during pregnancy only if potential benefit justifies potential risk to fetus.

NURSING MOTHERS:
Because no information is available on **Wytensin** excretion in human milk, it should not be given to nursing mothers.

PEDIATRIC USE:
Safety and effectiveness in children less than 12 years of age have not been demonstrated; use in this age group cannot be recommended.

Adverse Reactions:
Incidence of adverse effects was ascertained from controlled clinical studies in U.S. and is based on data from 859 patients on **Wytensin** for up to 3 years. There is some evidence that side effects are dose-related.

Following table shows incidence of adverse effects in at least 5% of patients in study comparing **Wytensin** to placebo, at starting dose of 8 mg b.i.d.

Adverse Effect	Placebo (%) n = 102	Wytensin (%) n = 109
Dry mouth	7	28
Drowsiness or sedation	12	39
Dizziness	7	17
Weakness	7	10
Headache	6	5

In other controlled clinical trials at starting dose of 16 mg/day in 476 patients, incidence of dry mouth was slightly higher (38%) and dizziness was slightly lower (12%), but incidence of most frequent adverse effects was similar to placebo-controlled trial. Although these side effects were not serious, they led to discontinuation of treatment about 15% of the time. In more recent studies using an initial dose of 8 mg/day in 274 patients, incidence of drowsiness or sedation was lower, about 20%.

Other adverse effects reported during clinical trials but not clearly distinguishable from placebo effects and occurring with frequency of 3% or less: Cardiovascular—chest pain, edema, arrhythmias, palpitations. Gastrointestinal—nausea, epigastric pain, diarrhea, vomiting, constipation, abdominal discomfort. Central nervous system—anxiety, ataxia, depression, sleep disturbances. ENT disorders—nasal congestion. Eye disorders—blurring of vision. Musculoskeletal—aches in extremities, muscle aches. Respiratory—dyspnea. Dermatologic—rash, pruritus. Urogenital—urinary frequency, disturbances of sexual function. Other—gynecomastia, taste disorders.

Drug Abuse and Dependence:
No dependence or abuse has been reported.

Overdosage:
Accidental ingestion caused hypotension, somnolence, lethargy, irritability, miosis, and bradycardia in two children aged one and three years. Gastric lavage and pressor substances, fluids, and oral activated charcoal resulted in complete and uneventful recovery within 12 hours in both. Since experience with accidental overdosage is limited, suggested treatment is mainly supportive while drug is being eliminated and until patient is no longer symptomatic. Vital signs and fluid balance should be carefully monitored. Adequate airway should be maintained and, if indicated, assisted respiration instituted. No data are available on **Wytensin** dialyzability.

Dosage and Administration:
Individualize dosage. A starting dose of 4 mg b.i.d. is recommended, whether used alone or with a thiazide diuretic. Dosage may be increased in increments of 4 to 8 mg/day every one to two weeks, depending on response. Maximum dose studied has been 32 mg b.i.d., but doses this high are rarely needed.

How Supplied:
Wytensin® (guanabenz acetate) Tablets, 4 mg and 8 mg, bottles of 100.

REHABILITATION IN ISCHEMIC HEART DISEASE

Approx. 500 pp., 188 figs. & tbls., large format 8½x11, 1982, $80.00

Edited by **William P. Blocker, Jr., M.D.,** F.A.C.P., Chief, Rehabilitation Medicine Service, V.A. Hospital, Houston, Assistant Professor of Physical Medicine, Baylor College of Medicine, Houston, and **David Cardus**, M.D., F.A.C.C., Professor of Physiology and Rehabilitation, Baylor College of Medicine, Houston, Texas.

Heavily illustrated, this volume presents 60 self-contained chapters dealing with *all* aspects of rehabilitation of the patient with ischemic heart disease. The 45 noted contributors discuss topics such as: designing a cardiac rehabilitation center; methods of rehabilitation for the stroke patient, amputee, spinal cord injury patient who has had a heart attack; equipment needs for a cardiac rehabilitation center; and legal responsibilities of the physicians and therapists.

All major aspects, from epidemiology and pathogenesis through prevention and education are covered, including ambulatory monitoring of electrocardiogram and blood pressure; evaluation of degree of disability; and pathogenesis of atherosclerosis. This book contains the *most complete* list of cardiac risk factors to be found in any text. This encyclopedic guide to the total care and rehabilitation of cardiac patients is written for *every* member of the cardiac rehabilitation team.

CONTENTS

PREFACE

PART I. EPIDEMIOLOGICAL ASPECTS 1. Statistical Studies: *William P. Blocker, Jr., M.D.* **2.** Coronary Risk Factors: *William P. Blocker, Jr., M.D.* **3.** Socioeconomic Factors: *Eleanor H. Kyle*

PART II. PATHOGENIC ASPECTS 4. Pathogenesis of Atherosclerosis: *Russell Ross, Ph.D., and John A. Glomset, M.D.* **5.** Biochemical Manifestations of Ischemic Heart Disease: *Mark Entman, M.D., and Jeanie McMillin-Wood, Ph.D.* **6.** Pathophysiology of Ischemic Heart Disease: *Robert A. Chahine, M.D.*

PART III. CLINICAL ASPECTS 7. The Natural History Of Ischemic Heart Disease: *David Cardus, M.D.* **8.** Clinical Manifestations of Ischemic Heart Disease: *Don W. Chapman, M.D., W. Richard Cashion, M.D., James C. Costin, M.D., and William H. Spencer, III, M.D.* **9.** Complications of Ischemic Heart Disease: *William P. Blocker, Jr., M.D.*

PART IV. EVALUATIVE ASPECTS 10. Anatomy and Angiography of Coronary Vessels: *Paul K. Peterson, M.D.* **11.** Exercise-Stress Testing in Ischemic Heart Disease: *David Cardus, M.D.* **12.** Myocardial Imaging: *Arnold Nitishin, M.D.* **13.** Disability Evaluation of the Cardiac Patient: *William P. Blocker, Jr., M.D.* **14.** Assessment of Obesity in the Cardiac Patient: *David Cardus, M.D., and William P. Blocker, Jr., M.D.*

PART V. MANAGEMENT ASPECTS 15. Evolution of the Treatment and Rehabilitation of the Cardiac Patient: *William P. Blocker, Jr., M.D. and Martin Grabois, M.D.* **16.** Treatment of the Acute Myocardial Infarction and its Complications: *Frank G. Yanowitz, M.D.* **17.** Rationale for Cardiac Rehabilitation: *William P. Blocker, Jr., M.D.* **18.** A Blueprint for Cardiac Rehabilitation: *William P. Blocker, Jr., M.D.* **19.** Patient Selection for a Cardiac Rehabilitation Program: *William P. Blocker, Jr., M.D.* **20.** Stage I of Cardiac Rehabilitation: Acute Phase of Cardiac Rehabilitation: *William P. Blocker, Jr., M.D.* **21.** Rehabilitation Phase Home Cardiac Rehabilitation Program (Stage II): *Henry J. Ostermann* **22.** Stage III of Cardiac Rehabilitation: Cardiac Rehabilitation Ward Program: *William P. Blocker, Jr., M.D.* **23.** Stage IV of Cardiac Rehabilitation: Recovery and Outpatient Follow-up Program: *G. Harley Hartung, Ph.D., and Claude R. Youngblood, M.A.* **24.** Implementing the Exercise Prescription: *David Cardus, M.D.* **25.** Prescription for Cardiac Rehabilitation Program: *G. Harley Hartung, Ph.D.* **26.** Monitoring of the Cardiac Rehabilitation Program by Electrocardiogram Telemetry: *Robert W. Dahl* **27.** Electrocardiogram Monitoring During Exercise and Factors Influencing its Interpretation: *Liep Hian Tjeng, M.D.* **28.** Electrocardiographic and Blood Pressure Ambulatory Monitoring: *William P. [illegible] TAKES THE TREADMILL THREE STEPS AHEAD.

e's a new standard for tread-
ence. Not surprisingly, it
m the company who has set
standards for nearly 20 years.
aises its own mark with the
a new breed of treadmills
oller.

The Q-55.
rrow's treadmill today.

Q-55 doesn't just set the
vances the state-of-the-art
new level.
eadmill has ever been quieter.
breakthrough makes this
t transmission on record.
eadmill has ever been more
Q-55 will level itself. (See
f. Slide a book under one
ts new, larger drums offer
cking.
eadmill has ever been more
Its sleek, low-profile
s the runner more room
r. And every surface is
r easy care.

The Q-65.
Engineered to be a workhorse.

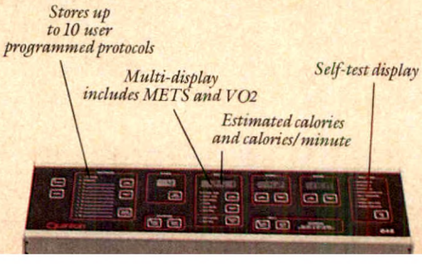
For heavy-duty demands, Quinton created a heavy-duty performer: the Q-65. Its longer length and three-horsepower motor make it ideal for rigorous testing or training.

And like its smaller brother, the Q-65 is built to give you top quality performance year after year.

The 645.
Smart treadmill control.

Now you've seen the muscle, meet the brains: Quinton's 645, our optional programmable treadmill controller. Advanced microprocessor technology make it the most sophisticated controller ever available.

Its "smart" electronics let it store up to ten user programmed protocols—each with up to 99 different stages. It can calculate METS and VO^2, plus calories per minute and cumulative calories. It even tells you when something's wrong. And its human-engineered panel makes it extraordinarily simple to operate.



The Q Series from Quinton. Treadmill technology that's out front—but not out of reach. Find out more. Call or write Quinton Instrument Company, 2121 Terry Ave., Seattle, WA 98121, 1-800-426-0347, telex 328840. Distributed worldwide.

FOR ANGINA PROPHYLAXIS*

SUSTAINED RELEASE
2.5, 6.5, 9.0 mg CAPSULES

NITROSTAT® SR
(nitroglycerin capsules)

■ complementary therapeutic effect: nitrates and beta-adrenergic blocking agents reduce myocardial oxygen demand by different mechanisms

Mechanism I: Nitrates reduce myocardial oxygen requirement by acting on systemic circulation. Their vasodilator action decreases venous return and systemic arterial resistance, thus improving the balance between the need and supply of oxygen. Reduction in the myocardial oxygen requirement appears to be the major action of nitrates in relieving typical angina. However, selective dilatation of large coronary vessels by nitrates may be the primary mechanism by which they benefit patients with angina due to coronary spasm.[1]

Mechanism II: In contrast, beta-blockers block the beta receptor sites in the heart itself. They work by reducing the heart rate and the force of contraction, thereby lowering oxygen demand. In addition to cardiac output and heart rate, blood pressure is also decreased.

Beta-blockers may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction.

■ diminished side effects: some of the negative aspects of the effects of each drug are reduced. For example, concomitant nitrates oppose the increased ventricular size, filling pressure, and end-diastolic pressure caused by beta-adrenergic antagonists.[1]

The effects of NITROSTAT® SR and a beta-blocker are complementary. The result can be improved therapy for angina prophylaxis.

■ all day and all night prophylactic action with just two or three daily doses*

How Supplied: 2.5-mg and 6.5-mg strengths, in bottles of 60 and 100 capsules. Also, 9.0-mg strength, in bottles of 60 capsules.

Please see next page for brief summary of prescribing information.

NITROSTAT® SR...Backed by the experience and reputation of PARKE-DAVIS

*Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows. "Possibly" effective: For the management, prophylaxis or treatment of anginal attacks. Final classification of the less-than-effective indication requires further investigation.

REFERENCE: 1. Needleman P, Johnson EM Jr: Vasodilators and the treatment of angina, in Gilman AG, Goodman LS and Gilman A (eds): Goodman and Gilman's The Pharmacological Basis of Therapeutics, ed 6. New York, Macmillan Publishing Co, Inc, 1980, pp 819-833.

Before prescribing, please
see full prescribing information.
A Brief Summary follows:

INDICATION: Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indication as follows.

"Possibly" effective: For the management, prophylaxis or treatment of anginal attacks.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATIONS:
Acute or recent myocardial infarction, severe anemia, closed-angle glaucoma, postural hypotension, increased intracranial pressure and idiosyncrasy to the drug.

WARNINGS:
Capsules must be swallowed.
FOR ORAL, NOT SUBLINGUAL USE.
Nitrostat SR Capsules are not intended for immediate relief of anginal attacks.

PRECAUTIONS:
Intraocular pressure may be increased; therefore, caution is required in administering to patients with glaucoma. Tolerance to this drug and cross-tolerance to other organic nitrites and nitrates may occur. If blurring of vision, dryness of mouth or lack of benefit occurs, the drug should be discontinued.

ADVERSE REACTIONS:
Severe and persistent headaches, cutaneous flushing, dizziness and weakness. Occasionally, drug rash or exfoliative dermatitis, and nausea and vomiting may occur; these responses may disappear with a decrease in dosage. Adverse effects are enhanced by ingestion of alcohol, which appears to increase absorption from the gastrointestinal tract.

DOSAGE AND ADMINISTRATION:
Administer the smallest effective dose 2 or 3 times daily, at 8- to 12-hour intervals, unless clinical response suggests a different regimen. Discontinue if not effective. 0883G010

Role of Myocardial Ischemia in the Genesis of Stress-Induced S-T Segment Elevation in Previous Anterior Myocardial Infarction

HENRY GEWIRTZ, MD, MICHAEL SULLIVAN, MSEE, GEORGE O'REILLY, BSc, STEVEN WINTER, MD, and ALBERT S. MOST, MD

This study tests the hypothesis that myocardial ischemia is responsible for exercise-induced S-T segment elevation in patients with previous anterior myocardial infarction (MI). Exercise stress testing in conjunction with thallium imaging of the myocardium was performed in 28 patients with previously documented anterior MI. Thallium images were analyzed by computer for the presence of initial uptake defects and evidence of abnormal clearance of the isotope from the myocardium (that is, imaging evidence of ischemia). Total S-T segment elevation (ΣST) in precordial leads V_1 to V_6 at rest was subtracted from ΣST at peak stress in order to quantitate the extent of S-T elevation induced by stress (ΔST). Two groups of patients were identified; 1 with stress-induced S-T elevation (Group I, $\Delta ST \geq 4.0$ mm) and 1 without this abnormality (Group II, $\Delta ST < 4.0$ mm). Evidence of abnormal thallium washout from myocardial scan segments occurred in 12 of 15 Group I patients versus 9 of 13 Group II patients (difference not significant). In addition, abnormal tracer washout from anterolateral or septal scan segments occurred in 5 patients in each group. Likewise, abnormal thallium clearance from inferior or posterior scan segments occurred in 8 of 15 Group I patients versus 7 of 13 Group II patients (difference not significant). The patient with the greatest amount of stress-induced S-T elevation (S-T 11.5 mm) had no evidence of ischemia during the stress test. However, Group I patients did have larger anterolateral plus septal initial thallium uptake defect scores than did those of Group II (10 of 15 with defect score ≥ 350 in Group I versus 1 of 13 in Group II, $p < 0.002$). Similarly, resting left ventricular ejection fraction $\geq 30\%$ was present in only 4 of 15 Group I patients versus 13 of 13 in Group II ($p < 0.001$). Finally, multiple stepwise linear regression analysis demonstrated that ΔST correlated best with the extent of initial anterolateral plus septal thallium uptake defect score ($F = 17.3$, $p < 0.001$) and to a lesser extent with resting ejection fraction ($F = 5.2$, $p < 0.05$) and change in heart rate from rest to peak stress ($F = 8.1$, $p < 0.01$; corrected multiple correlation coefficient = 0.76, $p < 0.001$). Thus, in patients with previous anterior MI (1) exercise-induced myocardial ischemia occurs as often with as without S-T segment elevation, (2) myocardial ischemia is not required for the production of stress-induced S-T segment elevation, and (3) stress-induced S-T elevation primarily reflects the extent of previous anterior wall damage and to a lesser extent an increase in heart rate between rest and peak stress.

Persistent S-T segment elevation in anterior precordial leads is not uncommon after anterior myocardial infarction (MI)[1] and is a specific albeit insensitive indicator of underlying left ventricular aneurysm.[2–5] Although myocardial ischemia does not appear to play a role in the genesis of chronic S-T segment elevation in these patients,[6] the role of ischemia in exercise-induced additional or new S-T segment elevation is less clear. While previous investigators have stated that myocardial ischemia does not contribute to this phenomenon,[7,8] a recent preliminary report[9] as well as several older reports[10–12] indicate that ischemia may be involved. Accordingly, the present study was undertaken to test the hypothesis that myocardial ischemia is responsible for exercise-induced S-T segment elevation in anterior precordial leads in patients with previous anterior MI.

From the Rhode Island Hospital, Department of Medicine (Cardiology Section), and Brown University Program in Medicine, Providence, Rhode Island. Manuscript received August 27, 1982; revised manuscript received January 14, 1983, accepted January 17, 1983.

Address for reprints: Henry Gewirtz, MD, Rhode Island Hospital, 593 Eddy Street, Providence, Rhode Island 02902.

Methods

Patient population: The study population consists of 28 atients (27 men, 1 woman) with a mean age of 53 years (range 7 to 79). Patients were selected on the basis of a history of revious anterior MI documented by standard electrocardiographic and enzyme criteria. These patients represent a ubset of all patients referred to the cardiovascular Nuclear Medicine laboratory at Rhode Island hospital by their private hysician for clinically indicated thallium stress tests and esting multigated cardiac blood pool scans. Radionuclide tudies were performed within 1 month of each another in 15 atients and within 2 to 9 months (mean 5) in the remainder. The time between MI and thallium stress test ranged from 1.5 o 120 months (mean 13).

Exercise stress test protocol: Each patient underwent a ymptom-limited, maximal exercise stress test according to modified Bruce protocol. Before the stress test a 12-lead lectrocardiogram (ECG) was obtained along with an interval istory and physical examination with attention directed oward the cardiovascular system. Thallium stress tests were erformed on a bicycle ergometer (Warren E. Collins, Braintree, Massachusetts) with the patient in the upright osition. Exercise was begun at 150 kpm and was increased y 150 kpm every 3 minutes. Heart rate, blood pressure (cuff), nd 12-lead ECG were recorded at 2.5 minutes into each stage f exercise. The patients' medications were continued as rescribed. Seventeen patients were taking digitalis or diuretics or both at the time of the thallium stress test. Informed onsent to undergo an exercise stress test in conjunction with adionuclide imaging of the heart was obtained from each atient.

Analysis of electrocardiograms: Because patients with lectrocardiographic evidence of anterior MI frequently have recordial lead S-T segments that demonstrate continuous psloping from the J point and that merge imperceptibly with ne T wave, we measured S-T segment elevation at the J point ather than 80 ms after it. The P-R segment was used as the oelectric point for this measurement. S-T segment elevation precordial leads V_1 through V_6 was summed (ΣST) and the esulting value subtracted from the sum of S-T segment elevation in the same leads in the immediate poststress electrocardiogram. The absolute value of the difference (ΔST) indicates the magnitude of additional S-T segment elevation hich occurred with stress in each patient. The immediate oststress ECG was used to evaluate the response of the S-T gment to exercise, because records obtained at peak stress equently exhibited baseline drift and muscle artifact which ake it difficult to accurately measure S-T segment elevation. atients in whom the absolute value of ΔST was ≥ 4 mm were efined as having additional S-T segment elevation in response to stress. Those in whom <4 mm of additional S-T evation occurred were defined as having no additional S-T evation with stress. The method of electrocardiographic alysis was chosen to obtain as much information as possible om the 6 precordial electrocardiographic leads while eliminating the possibility that any patient would be classified as aving stress-induced S-T elevation on the basis of only slight hat is, ≤ 0.5 mm) changes in repolarization potentials in veral or even all precordial leads. Although this definition S-T elevation admittedly is arbitrary, it does have the adntage of (1) using data from all 6 precordial leads and (2) ing more conservative than criteria of previous investigators[7,8] who accepted ≥ 1 mm S-T segment elevation in only a ngle electrocardiographic lead as evidence of new or increased S-T segment elevation with stress.

Thallium imaging: data acquisition and analysis: One inute before discontinuation of exercise, 2 mCi of thallium-201 was injected intravenously. After injection of the isotope the patient continued to exercise for an additional minute and then stopped. Imaging, first in the anterior and then in the 50° left anterior oblique position, was begun 5 to 7 minutes after thallium injection. Delayed images were obtained 2 to 3 hours later. All images were acquired in a 128 by 128 computer matrix (Medical Data Systems, Ann Arbor, Michigan) for 300,000 counts and acquisition time was carefully noted. An Ohio Nuclear Series 420 gamma camera equipped with a parallel hole, general all purpose collimator was used for this purpose.

The computer also was used to analyze the thallium images for the presence and location of initial uptake defects and for changes in thallium activity over time. Image analysis was performed without knowledge of the results of the electrocardiographic response to stress. The method for analyzing the thallium scan was similar to that described by previous investigators.[13,14] In brief, the images were first "zoomed" into a 64 by 64 matrix and then smoothed using a commercially available 9-point smoothing algorithm. Scans were then background corrected using a modified bilinear interpolative technique.[15] Next a radial analysis routine was employed to assess both uptake and washout of thallium at each 6° arc along the myocardial images. Uptake or washout abnormalities or both were said to be present when 2 or more adjacent radii fell below 2 standard deviations of the mean value of thallium uptake or washout at a given radial location for normal patients (n = 14) studied in our laboratory. The intra- and interobserver agreement for this method of image analysis ranges between 77 and 80% in our laboratory.[16] Delayed washout of thallium from myocardial scan segments was taken as objective evidence of tracer redistribution,[17,18] and thus was used as an independent test for determining if (and where) myocardial ischemia occurred during the stress test. Scan segments exhibiting delayed washout of thallium have been shown to correspond well with regions of myocardium perfused by stenosed ($\geq 50\%$ luminal diameter reduction) coronary arteries.[13,16]

Radionuclide ventriculography: data acquisition and analysis: Resting multigated cardiac blood pool scans were obtained after in vivo labeling of the patients' red blood cells with 25 m Ci of technetium-99m pertechnetate. Commercially available software (MUGB program) was used for this purpose. Images were obtained in anterior and 45° left anterior oblique projections with an Ohio Nuclear Series 420 gamma camera equipped with a parallel hole, general all purpose collimator and interfaced with the MDS computer system. Images were acquired for 200,000 counts/frame in a 32 by 32 matrix. Left ventricular ejection fraction was determined from the left anterior oblique view, using commercially available software (MUGE program).

Statistical analysis: A stepwise linear multiple regression analysis was used to assess the significance of correlations between the extent of S-T segment elevation induced by stress and various other experimental parameters. The Fisher exact test was used to assess the statistical significance of 2 by 2 frequency distributions. All data are expressed as mean $\pm$ 1 standard deviation. P values <0.05 were considered statistically significant.

Results

Clinical and electrocardiographic data: In response to stress 15 of 28 patients developed ≥ 4 mm S-T segment elevation over and above that present on the resting tracing (Group I). The remaining 13 patients developed <4 mm S-T segment elevation in precordial leads V_1 through V_6 in response to stress (Group II).

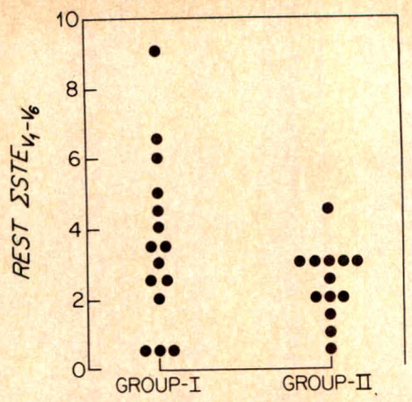

FIGURE 1. Total S-T segment elevation (ΣST) (mm) at rest in precordial leads V_1 through V_6 is plotted for each individual in the study. Note that ≤3.0 mm total S-T segment elevation at rest was more frequent in Group II patients (12 of 13 [92%]) than in those in Group I. Nevertheless, 7 of 15 (46%) Group I patients also had only limited (≤3.0 mm) S-T segment elevation at rest.

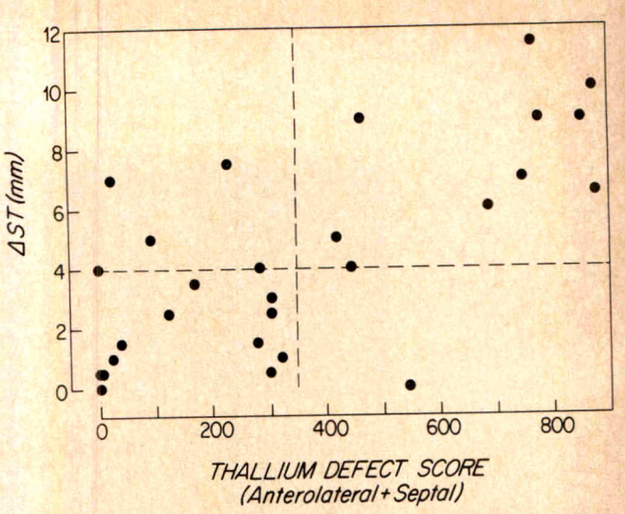

FIGURE 2. Combined anterolateral plus septal thallium scan initial uptake defect score (arbitrary units) is plotted on the abscissa versus ΔST on the ordinate for each patient. The correlation coefficient was 0.63 ($p < 0.001$). A defect score >350 was present in only 1 of 13 (8%) Group II patients versus 10 of 15 (67%) in Group I ($p < 0.005$).

Concomitant S-T segment depression ≥1 mm at 80 ms after the J point occurred in inferior limb leads (II, III, and aVF) or lateral precordial leads (V_5 and V_6), or both, in 7 patients (3 in Group I versus 4 in Group II; p not significant [NS]). The change in heart rate between rest and peak stress did not differ significantly between the 2 groups (60 ± 21 min^{-1} in Group I versus 47 ± 27 min^{-1} in Group II). Furthermore, 8 of 15 patients in Group I attained 85% of maximal age-predicted heart rate in comparison with 3 of 13 Group II patients (p = NS). Twelve patients experienced angina pectoris during the stress test (7 in Group I versus 5 in Group II). Similarly, 9 of 15 patients in Group I were taking digitalis at the time of their stress test in comparison with 6 of 13 in Group II. Diuretics were taken by 7 patients in Group I versus 5 in Group II. Total S-T segment elevation in precordial leads V_1 through V_6 at rest was >3 mm in 8 of 15 patients in Group I in comparison with only 1 of 13 patients in Group II ($p < 0.01$). However, there was overlap between the 2 groups in this regard (Fig. 1) and there was no correlation between ΣST at rest and ΔST in response to stress.

Imaging data: An initial anterolateral and/or septal thallium uptake defect was present in 14 of 15 Group I patients and in 10 of 13 Group II patients. Evidence of thallium redistribution (that is, delayed or slow washout of isotope over the course of time) occurred in 12 of 15 Group I patients and in 9 of 13 Group II patients. Also, evidence of thallium redistribution into anterolateral or septal scan zones occurred in 5 patients in each group. Likewise, redistribution into inferior or posterior scan zones occurred in 8 of 15 Group I patients and in 7 of 13 Group II patients. However, patients in Group I had higher combined anterolateral plus septal thallium initial uptake defect scores (Fig. 2) than did patients in Group II (combined score >350 arbitrary units in 10 of 15 Group I patients versus 1 of 13 Group II patients, $p < 0.002$). Furthermore, only 4 of 15 Group I patients had resting ejection fractions ≥30% (Fig. 3) in comparison with 13 of 13 Group II patients ($p < 0.001$). Stepwise linear multiple regression analysis demonstrated that ΔST correlated best with size of initial anterolateral plus septal scan defect ($F = 17.3$, $p < 0.001$) and to a lesser extent with resting ejection fraction ($F = 5.2$, $p < 0.05$) and change in heart rate from rest to peak stress ($F = 8.1$, $p < 0.01$). The corrected multiple correlation coefficient (r) for the regression of ΔST on size of initial anterolateral plus septal scan defect score, resting ejection fraction, and change in heart rate was 0.76, $F = 13.5$, $p < 0.001$.

Discussion

In an earlier study the extent of S-T segment elevation in patients with persistent S-T segment elevation after anterior MI was not altered by interventions that modified myocardial oxygen supply-demand balance.[6]

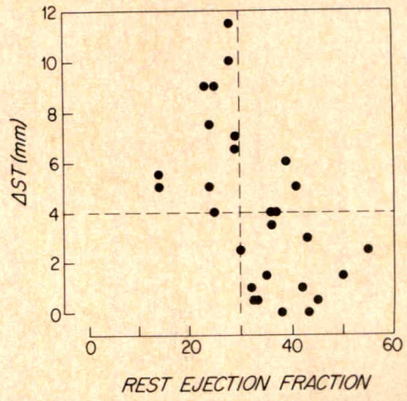

FIGURE 3. Resting left ventricular ejection fraction is plotted on the abscissa versus ΔST on the ordinate for each individual in the study. The correlation coefficient was − 0.52 ($p < 0.01$). All patients in Group II had ejection fractions ≥30%, versus only 4 of 15 (27%) in Group I ($p < 0.001$).

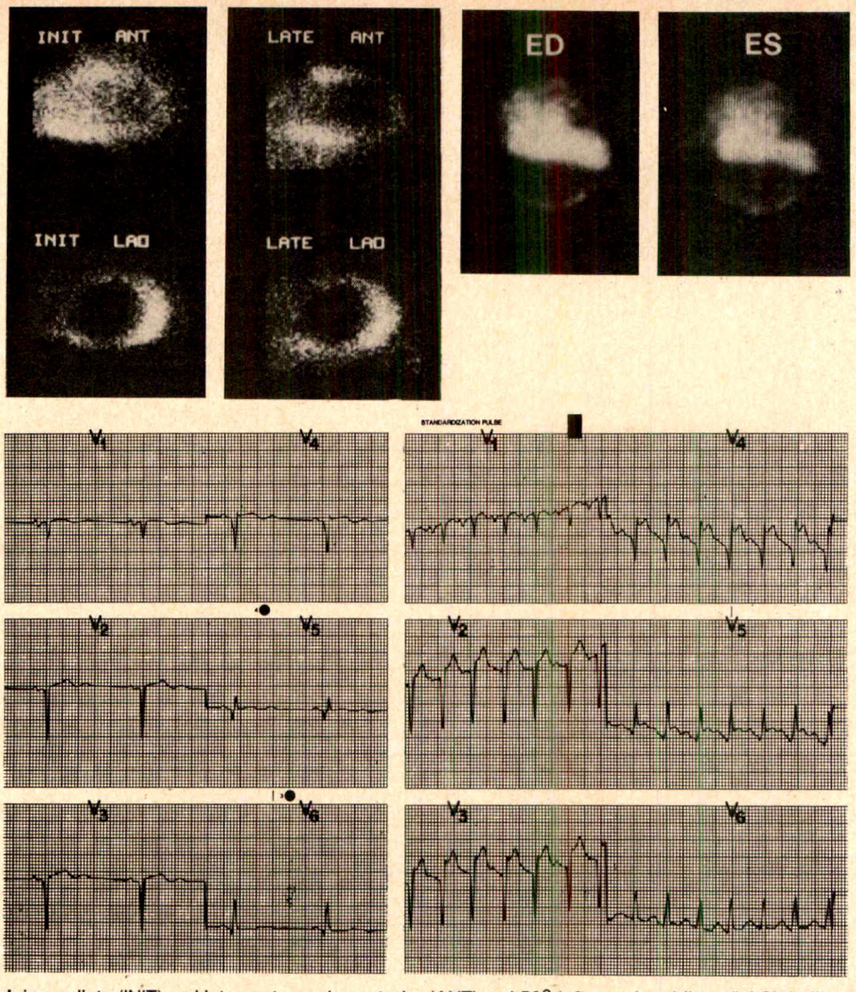

FIGURE 4. Top left panel, immediate (INIT) and late postexercise anterior (ANT) and 50° left anterior oblique (LAO) thallium images from the patient with the highest value of ΔST observed in the study. Note the extensive initial uptake defect involving anterolateral, apical, septal, and apical-inferior scan segments in the anterior and LAO projections. The initial scans also demonstrate dilation of the left ventricle and increased tracer uptake by the lungs in the anterior view. The latter finding suggests the occurrence of left ventricular failure during the stress test.[21] **Top right panel,** end-diastolic (ED) and end-systolic (ES) images (anterior view) from the patient's resting multigated cardiac blood scan. The left ventricle is enlarged and exhibits an obvious aneurysm at its apex with extension along the anterolateral and inferior wall. **Bottom panel,** rest (**left**) and peak stress (**right**) precordial leads V_1 through V_6 of the electrocardiogram are shown here for the patient with the highest value of ΔST observed in the study. Marked S-T elevation was induced by stress in leads V_2 through V_5 even though only modest S-T segment elevation was present on the resting trace.

Accordingly, it was concluded that chronic myocardial ischemia was unlikely to be responsible for this electrocardiographic abnormality. However, the observation that resting S-T segment elevation in these patients is not related to myocardial ischemia does not exclude the possibility that additional (or new) S-T elevation is caused by stress-induced myocardial ischemia. In addition, the observation that stress-induced S-T segment elevation in patients with previous anterior MI may be abolished after successful coronary bypass surgery also suggests a possible role for myocardial ischemia in this phenomenon.[9] However, the results of the present study indicate that myocardial ischemia is not sufficient by itself to cause additional S-T segment elevation in patients with previous anterior MI. Indeed, although 21 of 28 patients studied had evidence of abnormal myocardial washout of thallium (that is, imaging evidence of myocardial ischemia[17,18]), only 11 of 21 (52%) exhibited evidence of increased or new S-T segment elevation during the stress test. Furthermore, the patient who exhibited the greatest degree of S-T segment elevation in response to stress (ΔST = 11.5 mm) had no evidence of thallium redistribution in either anterior or left anterior oblique images (Fig. 4). Thus, although we cannot exclude the possibility that ischemia may contribute to additional or new S-T segment elevation during stress testing in some patients with previous anterior MI, clearly this phenomenon (that is, stress-induced S-T segment elevation) may occur in the absence of any evidence of myocardial ischemia.

Although this study was not designed specifically to determine the precise mechanism responsible for stress-induced new or increased S-T segment elevation in patients with previous anterior MI, data suggest that the following factors may be operative. First, there was a trend for patients with more extensive uptake defects

on thallium scans to exhibit increased S-T segment elevation in response to stress (Fig. 2). Thus, patients who exhibited ≥4 mm additional S-T elevation (Group I) also were more likely to have larger thallium initial defect scores for the anterolateral plus septal scan zones in comparison with patients with <4 mm additional S-T segment elevation (Group II). Similarly, Group I patients tended to have lower left ventricular resting ejection fractions than did those in Group II (Fig. 3), an observation that also is consistent with more extensive myocardial damage in the former group in comparison with that in the latter group.

The mechanism by which more extensive left ventricular damage contributes to increased S-T segment elevation during stress is unclear. However, it is known that body surface potentials are increased by increases in left ventricular volume (Brody effect[19,20]). Because patients with increased S-T segment elevation with stress tend to have more extensive left ventricular damage (Fig. 4), they also may be more likely to develop left ventricular dilation in response to stress than are patients in whom myocardial damage is less extensive. Thus, differences in stress-induced changes in left ventricular volume could potentially account for differences observed between the 2 groups in the extent of S-T segment elevation which occurs during exercise. However, additional studies are required to test this hypothesis.

The clinical implications of the data may be summarized as follows. Myocardial ischemia as evidenced by abnormal clearance of thallium from myocardial scan segments is common in patients with previous anterior MI. Increased S-T segment elevation in response to stress testing also is relatively common and (as defined in this study) occurred in 50% of the patients. However, the relation between the 2 events (that is, myocardial ischemia and increased S-T segment elevation) appears more coincidental than causal. Specifically, although 12 of 15 patients with increased S-T segment elevation had evidence of ischemia on thallium study, 10 of 21 patients with ischemia on thallium study failed to exhibit increased S-T segment elevation during stress. Furthermore, as just pointed out, the individual with the greatest increase in S-T segment elevation had no evidence of ischemia on the thallium scan nor did he complain of chest discomfort during the test. Accordingly, although ischemia could contribute to increased S-T segment elevation during stress in some patients, it clearly is not required. Furthermore, ischemia frequently occurs in the absence of increased S-T segment elevation in this group of patients. However, increased S-T segment elevation in response to stress does indicate the presence of extensive left ventricular damage and generally more severe impairment of resting left ventricular systolic function. Finally, differences in the extent of left ventricular dilatation induced by stress may be responsible for differences in S-T segment response to stress in patients with previous anterior MI.

Enzymatic Estimation of Myocardial Infarct Size Whe Early Creatine Kinase Values Are Not Available

JANET L. SMITH, MD, H. DIETER AMBOS, HERMAN K. GOLD, MD, JAMES E. MULLER, MD, W. KENNETH POOLE, PhD, DANIEL S. RAABE, Jr., I ROBERT E. RUDE, MD, EUGENE PASSAMANI, MD, EUGENE BRAUNWALD, M BURTON E. SOBEL, MD, ROBERT ROBERTS, MD, and the MILIS Study Grou

Estimates of myocardial infarct (MI) size based on plasma creatine kinase (CK) are used widely for prognosis and in the assessment of therapy designed to salvage ischemic myocardium. However, if the initial plasma CK activity is elevated, MI size will be underestimated. To determine the impact of loss of early CK values on estimates of MI size and to develop a procedure to compensate for it, estimates of MI size based on complete and incomplete MB and total CK time-activity curves from 120 patients (experimental group) were compared. Estimates of MI size based on data inclusion intervals beginning at 24, 12, 8, and 4 hours before peak CK were 11, 14, 23, and 47% smaller than values based on complete CK curves, but the correlation was good between complete and incomplete estimates of MI size at any given interval, with r values ranging from 0.91 to 0.98. The derived correction fact then prospectively applied to a new popu = 25) with complete CK curves to compe purposely omitted early CK values. The c estimates of MI size were within 7% of tho on the complete CK curves. Similar resu obtained for transmural and nontransm anterior or inferior MI. Thus, if peak plasr known, underestimation of MI size can pensated for despite the unavailability of values. Since >90% of patients presen plasma CK has reached its peak (24 hours can be obtained in nearly all patients. Thu able to correct for unavailable early CK makes MI size a more widely applicable for use in clinical trials and patient manag

Myocardial infarct (MI) size estimated from serial changes in plasma creatine kinase (CK) is a frequently used endpoint for assessment of interventions designed to influence ischemic myocardium.[1–11] Enzymatic estimates of MI size correlate with short- and long-term prognosis,[12–16] the severity of ventricular dysfunction,[17,18] the incidence of ventricular arrhythmias,[19] and the incidence of heart failure.[20,21] Their reliability has been confirmed in postmortem studies demonstrating concordance between enzymatic and morphometric estimates.[15–22] Availability of enzymatic est MI size permit assessment of therapeutic inte with smaller numbers of patients than requ alternative conventional endpoints such as m The widespread availability of convenient, r quantitative CK isoenzyme assays has made e estimation of MI size widely applicable.[24,25]

In 1978 a randomized, multicenter study limitation of infarct size (MILIS) was implem the National Heart, Lung, and Blood Institute the effects of propranolol and hyaluronidase o in patients with acute MI. The primary endpo study is MI size determined by analysis of seri CK changes. Several other variables are also including ventricular function and rhythm. MILIS will not be completed until 1983, inte ysis of data, without stratification of patie treatment or control groups and without unl indicated that in approximately 20% of the pat initial plasma CK value was elevated. The

available earlier values leads to underestimation of MI size. Elevation of CK activity in the initial CK sample possibly occurs even more frequently in the general hospital patient population.

This study characterizes the quantitative impact of loss of early CK data on estimates of MI size and develops and evaluates a practical correction process to compensate for early data loss. Complete plasma CK curves from a large sample of patients were analyzed to provide estimates of MI size based on complete sets of data. The effect on estimates of omitting early CK values was then determined. The correction method was validated prospectively in a separate group of patients with acute MI.

Methods

The clinical centers participating in MILIS are the Brigham and Women's Hospital, the Massachusetts General Hospital (Boston, Massachusetts), the University of Vermont (Burlington, Vermont), Barnes Hospital (St. Louis, Missouri), and Parkland Memorial Hospital (Dallas, Texas). All patients entering the cardiac care units of these hospitals are considered potential participants. Patients eligible for enrollment must (1) have typical chest pain lasting for ≥30 minutes; (2) have electrocardiographic changes consisting of new ST-T segment changes ≥1 mm, new Q waves, or new left bundle branch block; and (3) be admitted within 18 hours of onset of symptoms. Patients are excluded for any of the following reasons: (1) age >75 years; (2) Killip class IV congestive heart failure; (3) pregnancy; (4) advanced or terminal illness; (5) cardiomyopathy, acute cerebrovascular disease, or concomitant use of an artificial pacemaker; (6) myocardial infarction within 2 weeks; (7) physical or psychological inability to cooperate with the study, or (8) concurrent participation in another research protocol.

Data are collected in a standardized fashion at all clinical centers. Laboratory data are obtained and processed at separate reference laboratories, and blinded with respect to patient stratification and treatment. All data are collated and analyzed at an independent data coordinating center with tabulation identified only by patient number.

Patient population: Patient selection for the present study was based solely on the characteristics of the plasma total and MB CK time-activity curves. All had complete curves, defined as those with an initial total CK value of ≤100 IU/liter and an initial MB CK value of ≤12 IU/liter, inclusion of all values including peak, and subsequent return to a value at or below the initial baseline value.

Initial assessment and data analysis were performed on curves from 120 patients enrolled in MILIS whose plasma CK curves met these criteria (the experimental group). A second group of patients, referred to as the test group, consisted of an independently acquired sample of 25 patients with definite myocardial infarction and complete total and MB CK time-activity curves, admitted to the Barnes Hospital Cardiac Care Unit between August 1, 1978 and March 1, 1979. The test group included patients who were excluded from enrollment into MILIS primarily because of patient or physician refusal. The criteria for confirmation of myocardial infarction in this test group were the same as those used for MILIS, namely, typical serial elevations of plasma total and MB CK. MI was deemed transmural if new Q waves developed and nontransmural if electrocardiographic changes were restricted to the ST-T segment. MI was designated as anterior when diagnostic changes involved leads V_1 to V_5, and inferior when they involved 2 or more of leads 2, 3, or aVF.

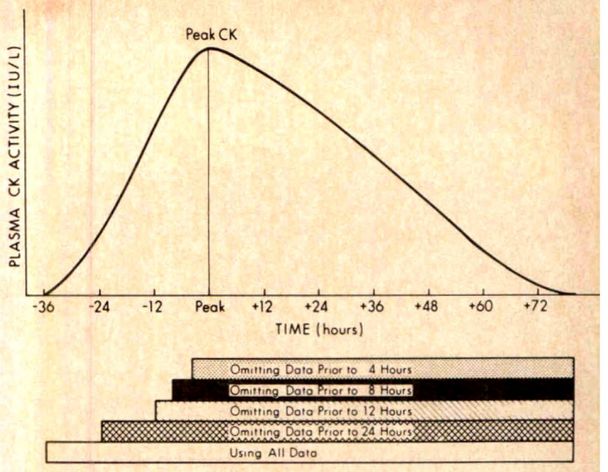

FIGURE 1. The approach used to determine the effect of omitting earl CK data on estimates of MI size. As indicated, peak plasma CK activit was used as the reference point, and estimates of MI size based o inclusion of data beginning 4, 8, 12, or 24 hours before peak wer compared with estimates on all values.

Collection and analysis of CK and MB CK samples Blood samples for total and MB CK analysis were draw hourly for the first 4 hours after admission, every 2 hours fo the next 4 hours, and every 4 hours subsequently, for an in terval of 96 hours from the time of initial sample. Sample were then obtained every 12 hours until hospital discharge Blood samples were drawn into a tube containing ethyleneg lycoltetraacetic acid (5 m*M*) and centrifuged for 10 minute at 2,500 *g* to remove the cellular components. Before storage beta-mercaptoethanol (final concentration = 10 m*M*) wa added and samples were stored at −20°C. Samples wer shipped on dry ice to the MILIS CK Core Laboratory a Washington University. Selected samples are returned peri odically to the clinical units and after storage reshipped to th CK Core Laboratory for repeat analysis. To date, results o CK analysis before and after shipping and storage remai within 5%. Plasma total CK activity was determined spec trophotometrically by the method of Rosalki.[26] MB CK wa analyzed quantitatively by 2 methods: a glass bead batc absorption assay[27] and a radioimmunoassay.[28] For estimatio of MI size, all CK values before return to baseline usuall within 96 to 144 hours were included. The MB CK value utilized for estimating MI size were those determined by th glass bead method.

Analytical approach: Total and MB plasma CK curve were analyzed separately, but the approach employed wa identical. Peak plasma CK activity was identified and the tim to peak determined for each curve, defined as the interva from initial elevation of plasma total or MB CK above baselin to the time of occurrence of peak CK activity. To determin the impact of loss of early enzyme data on values for MI size several estimates of MI size were computed for each patien in the experimental group. Estimates based on all data point are termed, for convenience, complete estimates. Subse quently, separate estimates of MI size (incomplete estimates were obtained based on inclusion of only the initial 24, 12, 8 or 4 hours of data before peak (Fig. 1). Thus, 5 estimates of M size were obtained for each patient, 1 based on the complet CK curve and the others based on incomplete data sets. In complete estimates at each interval of data exclusion wer compared with complete estimates. The extent of underesti mation of MI size obtained from each set of incomplete esti

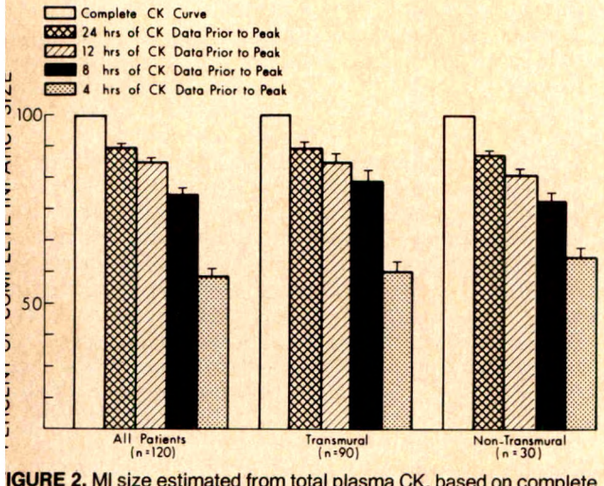
nates was expressed as the percentages of the corresponding omplete estimates. The inverse of percentages were consid-red to be potential "correction factors." An identical analysis vas performed on complete curves from 25 other patients tudied prospectively and referred to as the test group.

To assess utility of the correction factors, early data were mitted from the plasma CK curves in the test group. Esti-nates of MI size based on the incomplete curves were adjusted y utilizing the correction factors derived from the experi-nental group. The adjusted estimates were then compared vith estimates from the complete curves in the test popula-ion.

MI size based on total or MB CK was estimated as previ-usly described in detail.[28] Complete and incomplete esti-nates of MI size were analyzed for all patients and for those atients with anterior, inferior, transmural, and non-ransmural MI to determine whether site and locus of MI in-luenced the values of the derived correction factors.

Statistics: Values are expressed as a mean ± standard de-iation unless indicated otherwise. The *t* test for unpaired amples was used to compare intergroup data. Linear re-gression analysis was performed to determine the correlation coefficients for relations between complete and incomplete estimates of MI size.



IGURE 2. MI size estimated from total plasma CK, based on complete nd incomplete CK data, is compared for the total population in the xperimental group (all patients) and for patients with transmural and ontransmural infarction. The results show that a similar underesti-nation of MI size (shown on the **ordinate**) occurs with transmural and ontransmural MI for each specific interval of data included.

Results

Experimental group—effects of omission of early data: The mean values for complete and incomplete estimates of MI size in the experimental group are shown in Table I. As indicated by the high values of the correlation coefficients, estimates for each interval of data exclusion correlate closely with complete estimates. Mean MI size, based on complete total CK curves, was 44 ± 3 CK-g-Eq, with a range of 4 to 146, representative of the range for the overall MILIS population and similar to previously published results.[13,16] Initial plasma CK elevation occurred 5.8 ± 0.4 hours after the onset of symptoms, with a range of 1 to 11. Peak plasma CK occurred 23 ± 1 hours after the initial CK elevation, that is, an average of 29 hours after the onset of symptoms (range 13 to 33). The percent difference between complete and incomplete estimates of MI size is illustrated in Figure 2. Estimates of MI size based on CK data beginning only 24 hours before peak CK averaged 40 ± 3 CK-g-Eq, that is, 11 ± 1% less than the corresponding value based on complete data. Estimates based on CK data beginning only 12 hours before peak averaged 38 ± 4 CK-g-Eq, that is, 14 ± 2% less than the complete data estimate. Estimates based on CK data beginning only 8 hours before peak averaged 34 ± 4 CK-g-Eq, that is, 23 ± 2% less than the corresponding complete data estimate. An even more marked underestimation of 47 ± 2% resulted when data beginning only 4 hours before peak were employed.

Striking differences were evident between estimates of MI size based on MB CK from incomplete compared with complete data sets, as shown in Table II. Nevertheless, the correlation between the values for any given interval and complete estimates was close. Complete estimates based on MB CK averaged 43 ± 3 CK-g-Eq, with a range of 1 to 80. Initial plasma MB CK elevation occurred 5.8 ± 0.4 hours after the onset of symptoms, with a range of 1 to 11, similar to that for total CK. Peak plasma MB CK occurred 29 ± 1 hours after the onset of symptoms. The mean difference between complete

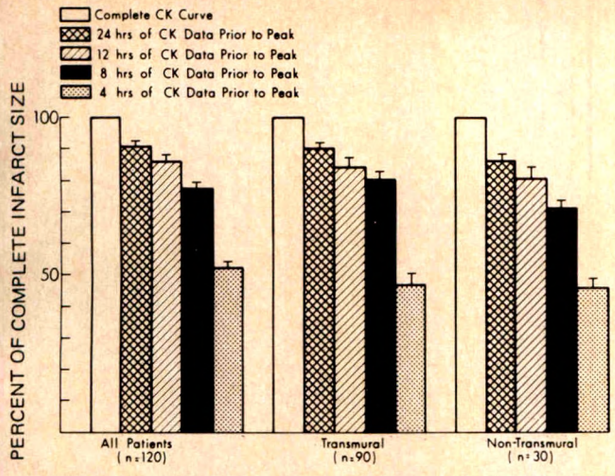


FIGURE 3. Infarct size estimated from MB CK, based on complete and incomplete CK data, is compared for the total population in the experimental group (all patients) and for patients with transmural and nontransmural MI. A similar underestimation of MI size (shown on the **ordinate**) occurs with transmural and nontransmural infarction for each specific interval of data included.

TABLE III Comparison of Complete and Incomplete Estimates of MI Size in the Test Group

Onset of Interval of Data Inclusion	Infarct Size (CK-g-Eq)	Percent Underestimation	Correlation Between Estimates With Complete and Incomplete CK MB Curves (r)
Before initial CK elevation (all values)	40 ± 6	0	. . .
24 hours before peak CK	37 ± 5	8 ± 2	0.93
12 hours before peak CK	35 ± 5	15 ± 1	0.91
8 hours before peak CK	27 ± 3	25 ± 3	0.93
4 hours before peak CK	19 ± 3	51 ± 3	0.95
Before initial MB CK elevation (all MB CK values)	41 ± 7	0	. . .
24 hours before peak MB CK	38 ± 5	8 ± 1	0.91
12 hours before peak MB CK	35 ± 4	14 ± 1	0.92
8 hours before peak MB CK	26 ± 3	23 ± 1	0.95
4 hours before peak MB CK	18 ± 3	48 ± 1	0.93

and incomplete estimates of MI size with data from only the intervals embracing 24, 12, 8, and 4 hours before peak MB CK were 10.5 ± 0.4, 14 ± 1, 24 ± 2, and 49 ± 2%, as shown in Figure 3.

In the experimental group, MI was transmural in 90 patients and nontransmural in 30. Mean MI size based on total plasma CK in patients with transmural MI averaged 47 ± 4 CK-g-Eq, significantly greater than that in patients with nontransmural MI (22 ± 4 CK-g-Eq, $p < 0.004$). A similar difference was observed for estimates based on MB CK (45 ± 2 CK-g-Eq for transmural and 23 ± 2 CK-g-Eq for nontransmural MI, $p < 0.002$). No significant difference in this variable was observed among patients with anterior, inferior transmural, or anterior or inferior nontransmural MI (Table III).

The differences in the time to peak CK or to peak MB CK in patients with transmural compared with nontransmural MI did not significantly change the derived correction factors. Underestimation of MI size with data from only 24, 12, 8, or 4 hours before peak averaged 10, 15, 21, and 50% in patients with transmural compared with 13, 19, 27, and 45% among those with nontransmural MI. Corresponding percentages of underestimations where MB CK values were used were 10, 16, 20, and 53% for transmural and 14, 19, 29, and 54 for nontransmural MI. Although the percentage of underestimation for both MB CK and total CK for nontransmural was somewhat greater than that in transmural MI and in the group as a whole, the mean values were not statistically different.

Test group: Analysis of the test group is shown in Table IV for total and MB CK. Complete estimates of MI size in the test group averaged 40 ± 6 CK-g-Eq, with a range of 4 to 121, which was similar to values in the experimental group. The time to peak plasma total CK activity was 24 ± 1 hours. Incomplete estimates for the inclusion intervals of only 24, 12, 8, and 4 hours of data before peak total CK averaged 8 ± 2, 15 ± 1, 25 ± 3, and 51 ± 3%, that is, less than values for complete estimates. Again, the correlation was close between complete and incomplete estimates of MI size for any interval selected. The percentages of underestimation of MI size in the test group were virtually identical to those in the experimental group (Fig. 4).

Results of analysis of plasma MB CK curves for the test group are shown in Table IV. Mean values for complete estimates of MI size were 41 ± 7 CK-g-Eq, with a range of 2 to 80. The time to peak MB CK was 24 hours. The extent of underestimation of MI size at the selected intervals of omitted MB CK data was identical to underestimation in the total CK. The correlation between incomplete and complete estimates for any given interval was close.

The interval to peak CK in patients with transmural MI in the test group averaged 25 ± 1 hours, as opposed to 17 ± 2 for patients with nontransmural MI. These values are similar to those in the experimental group.

Correction of incomplete estimates: Figure 5 shows the relation between underestimation of MI size

TABLE IV Influence of Site and Type of MI on Time to Peak CK

Type and Site of Infarction	Patients (n)	Time to Peak CK (Hours)
Total population	120	23 ± 1
Transmural	90	25 ± 1
Nontransmural	30	17 ± 2
Anterior transmural	52	23 ± 1
Inferior transmural	38	25 ± 1
Anterior nontransmural	19	18 ± 2
Inferior nontransmural	11	16 ± 2

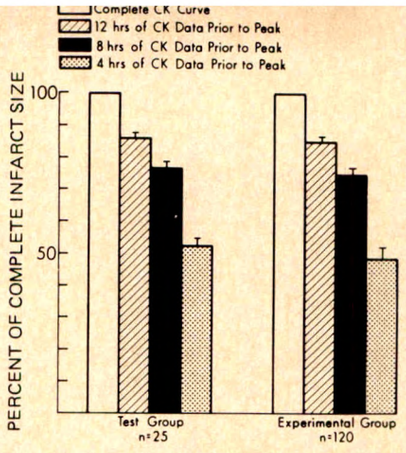

FIGURE 4. The extent of underestimation of MI size for complete and incomplete total CK curves in the test group compared with that observed in the experimental group. As is evident from the bar graph, the percent underestimation of MI size is virtually identical for each interval of data included for the 2 groups.

and the interval of inclusion of data. The figure illustrates that more than half of CK is released before the time of occurrence of peak plasma activity. The standard deviation for the correction factor for the shortest interval of inclusion of data, within 4 hours to peak, is 7%, as opposed to only 1.5% for the interval beginning 10 hours before peak. The rate of release of CK into plasma is slow during the initial 8 to 10 hours, but more rapid as the time to peak is approached. Thus, over the interval of 18 to 24 hours before peak, the curve is relatively flat, with underestimation of MI size based on exclusion of data before this interval consistently in the range of 10%. Inclusion of data beginning 24 hours before peak exhibits virtually the same underestimation and derived correction factor (Table V).

Correction formula: Corrected infarct size = incomplete infarct size % of projected infarct size ×100.

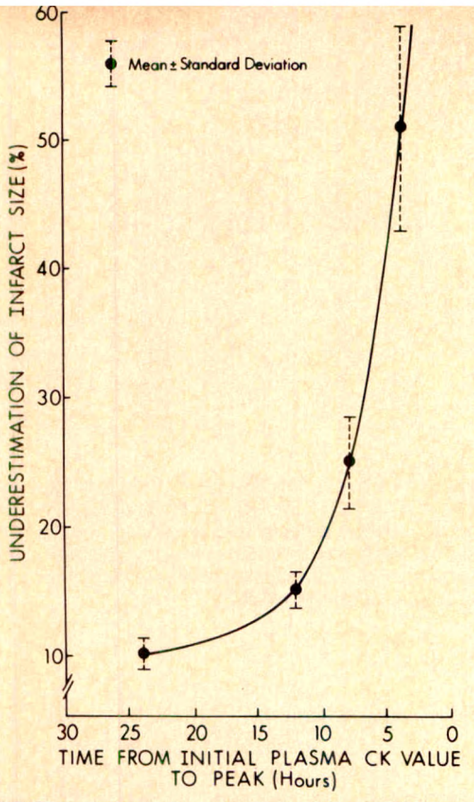

FIGURE 5. The relation between omission of early CK data and estimates of MI size with respect to the ascending plasma CK curve. As is evident from the graph, omission of CK data before 15 hours' peak CK activity has a minimum effect, with an underestimation of MI size of only about 10 to 22%. The effect on estimates increases exponentially as the time to peak decreases. Also shown are the means and standard deviations for each correction factor. The standard deviation does not exceed 7% for any correction factor.

Based on the relation evident in Figure 5, we expressed the percentage of complete estimates of MI size for incomplete estimates as a function of the time of occurrence of peak (Table V). The approach applies to all patients in whom the initially available plasma CK precedes the peak plasma CK activity by at least 2 hours.

With the correction procedure noted in Table V obtained from the experimental group, the estimates in the test group were corrected for 4 to 24 hours of data loss and the results compared with the estimates of MI size based on complete CK curves. Data for each patient are shown in Table VI. The values for corrected, incomplete estimates are very similar to the values estimates from the complete CK curve.

Discussion

In the present study, we have shown that omission or loss of early CK data leads to underestimation of MI size. The extent to which MI size is underestimated depends not only on how much data is missing, but also when acquisition begins with respect to variables of the CK curve. Analysis of the data indicates that approximately two thirds of the CK released into the plasma

appears within 24 hours after the initial CK elevation, corresponding to the mean interval to peak CK (Table VI). The rate of increase of plasma CK activity reflecting the rate of release of CK from the myocardium into the blood is not constant. The pattern of release conforms to a sigmoid curve with initially slow, followed by rapidly increasing release during 15 hours before plasma CK. Thus, in a patient with transmural MI and a representative CK curve with peak activity 24 hours after the onset of symptoms, a lag phase of 4 to 5 hours occurs during which essentially no measurable CK is released into the plasma. Subsequently, a 6- to 8-hour phase of slow release follows. Omission of data during these phases with the initial CK sample obtained 10 to 12 hours after the onset of symptoms results in underestimation of MI size but only by 10 to 12%. After this interval, however, release becomes rapid, and omission of data leads to marked underestimation of MI size.

The consistent pattern of CK release results in a close correlation between complete and incomplete estimates of MI size based on the same interval of data loss. With the use of 24 hours or the time of occurrence of peak CK as a reference point, the correction factors convert incomplete estimates to close approximations of complete ones, for both total and MB CK. Correction is equally applicable to anterior and inferior, transmural and nontransmural MI. The correction factors were derived from 120 patients with MI size ranging from 5 to 140 CK-g-Eq, a range similar to that observed for the MILIS population as a whole. The range of MI size is similar to that observed in 800 other patients admitted to Barnes Hospital before the initiation of the MILIS study. Application of the derived correction factors to a separate test sample corroborated their utility. Thus the present results indicate that if the time of occur rence of peak CK can be determined, MI size can b estimated accurately despite the absence of early CK data. In view of the estimated plasma MB CK half-lif of 6 to 8 hours, a sampling frequency of every 4 hour should be adequate for detection of peak plasma CK Peak plasma CK correlates reasonably well with MI siz but is less accurate than the total integrated release.[2] This is due to the nature of the plasma CK time-activity curve which does not conform to a bell-shaped curve but rather rises to a peak and exhibits a plateau o varying duration during which a significant amount o CK is released which is not reflected by the peak. Th correlation between peak plasma CK and MI size is goo if the plateau phase is of short duration, but is poor i prolonged.[30]

The approach developed provides a means to esti mate MI size in those patients in whom early CK value are missing. Its application should make it possible t obtain estimates of MI size in most patients hospitalize with MI. In the Barnes Hospital Cardiac Care Unit, 93% of patients are admitted before the plasma CK activity has reached a peak. In this MILIS population, 96% o patients are enrolled before the time of occurrence o peak CK. Thus, in clinical trials employing MI size a the endpoint, results from an appreciable number o patients who might otherwise have to be excluded should be available, reducing the total number of pa tients required for achieving desired statistical power In patients undergoing interventions such as strep tokinase-induced reperfusion where the plasma CK curve is significantly altered (namely more rapid releas

f CK), it may be necessary to derive the correction actor from complete curves to compensate for unvailable early values.

Serial Exercise Testing Up to 6 Years After Coronary Bypass Surgery: Behavior of Exercise Parameters in Groups With Different Degrees of Revascularization Determined by Postoperative Angiography

HELMUT GOHLKE, MD, CHRISTA GOHLKE-BÄRWOLF, MD, LADISLAUS SAMEK, MD, PETER STÜRZENOFECKER, MD, MARTIN SCHMUZIGER, MD, and HELMUT ROSKAMM, MD

To evaluate the behavior of exercise parameters in patients with different angiographically defined degrees of revascularization, serial exercise tests were analyzed in 435 patients 1 to 6 years after coronary artery bypass grafting (CABG). All patients had undergone postoperative angiography 2 to 12 months after CABG to determine the degree of revascularization achieved. Revascularization was complete in 182 patients (all significantly stenosed arteries had patent grafts), sufficient in 176 patients (at least the dominant artery supplying the left ventricle had a patent graft) and incomplete in 57 patients (the dominant artery supplying the left ventricle had a closed graft). Twenty patients had all grafts occluded. Exercise tolerance, angina-free exercise tolerance (angina threshold), maximal double product, prevalence of ≥0.1 mV exercise-induced S-T segment depression, and the prevalence of the combination of S-T segment depression plus angina pectoris were determined in serial exercise tests (average of 3.0 postoperative exercise tests per patient for a mean follow up of 3.5 years). Patients with complete, sufficient, and incomplete revascularization showed improvement of all exercise parameters for 6, 4, and 1 year after CABG, respectively. Patients with all grafts occluded had improvement of only some exercise parameters.

Five years after CABG, exercise tolerance was improved by 24 W ($p < 0.0005$) and 21 W ($p < 0.005$) in patients with complete and sufficient revascularization, respectively, and not improved in patients with incomplete revascularization or with all grafts occluded. The angiographically determined completeness of revascularization correlates with the extent and the duration of improvement of exercise parameters after CABG.

The improvement of effort angina in a large percentage of patients is well established at 6 to 12 months after coronary artery bypass grafting (CABG).[1–5] Relief of angina pectoris is associated with improvement in exercise tolerance and a change in the functional class according to the New York Heart Association classification as applied to angina by the Canadian Cardiovascular Society.[6] Although the grading according to the New York Heart Association classification is convenient, there is significant room for subjective interpretation of complaints by the patients and the physician. Exercise testing can provide more objective information on the physiologic state of the cardiovascular system after CABG, particularly when used in serial evaluation of patients after CABG. Few data are available on the results of serial exercise testing after CABG,[1,7,8] and there have been no studies reported on serial exercise testing in patients with different degrees of revascularization. The present study describes the results of serial exercise testing up to 6 years after CABG in patients with angiographically defined degrees of revascularization.

ographic evaluation of graft patency and determination of the degree of revascularization performed according to the criteria pointed out later; and (3) preoperative and postoperative exercise testing performed. Patients included in this study are not part of a randomized study.

CABG was performed after an intense trial of medical management under hospital conditions was unsuccessful in reducing anginal symptoms to an acceptable degree. Medical management (aside from vigorous efforts to eliminate risk factors) consisted of therapy with a combination of long-acting nitrates, a beta-blocking agent and a calcium antagonist, usually nifedipine.

Most patients had not been working for several months before CABG because of limiting symptoms or because of recent myocardial infarction with persisting angina. Angiography after CABG was offered to every patient during the study period; patients included in the study comprised 77% of all those under age 56 who underwent operation during the study period. Patients not included are those who refused postoperative angiographic evaluation, or those in whom exercise testing was not performed for a variety of reasons before or 1 year after surgery.

Angiographic Evaluation

Preoperative coronary angiography was performed using the Sones technique in the majority of patients (95%) and the Judkins technique in the remainder after sublingual nitroglycerin had been given. Angled caudocranial views were used routinely from 1974 on. Lesions in the coronary arteries were analyzed by measuring the reduction in luminal diameter. Postoperative angiography was performed using the Judkins technique in most patients (75%) and the Sones technique in the remaining patients. A vessel was considered adequately revascularized if the bypass showed no narrowing >50% of the luminal diameter of the grafted artery and if the grafted artery had no distal lesions of >50% luminal diameter reduction. Patients were classified into 4 groups according to the degree of revascularization as determined by postoperative angiography.

Definition of different degrees of revascularization: *Group I: Complete revascularization:* All significantly stenosed bypassable arteries were provided with an open graft: Bypassable diagonal branches of the left anterior descending artery and marginal or posterolateral branches of the circumflex artery and posterolateral branches of the right coronary artery also were considered if appropriate in size (that is, >1.2 mm). A graft was considered open if the luminal diameter of the graft was narrowed to no more than 50% of the luminal diameter of the grafted artery.

Group II: Sufficient revascularization: At least the bypass to the dominant vessel supplying the left ventricle was provided with an open graft. The vessel supplying the major portion of the left ventricle was considered the dominant vessel; this was the left anterior descending artery in most patients. Occasionally, an exceptionally large right coronary or circumflex artery could supply the major portion of the left ventricle (as estimated by the angiographer) and was considered the dominant vessel. A further bypass may be occluded or a significantly stenosed bypassable vessel was left ungrafted.

Group III: Incomplete revascularization: The dominant vessel supplying the left ventricle was significantly stenosed and the graft stenosed or occluded. At least one additional bypass was patent.

Group IV: All grafts were occluded.

Exercise Testing

All patients had undergone exercise testing before and 1 year after CABG. Thereafter exercise tests were scheduled at yearly intervals at the anniversary of the operation. All exercise tests were performed with an electrically braked bicycle ergometer (Siemens-Elema) with the patient in the supine position. A 12-lead electrocardiogram and blood pressure were recorded at rest and at 2-minute intervals. Exercise was begun with 25 or 50 W and the work load was increased every 2 minutes by 25 or 50 W until fatigue, severe dyspnea, angina pectoris, and ≥0.4 mV S-T segment depression occurred or 80% of the age predicted maximal heart rate was reached. The following features were analyzed: exercise tolerance, angina-free exercise tolerance (in watts [angina threshold]), maximal S-T segment depression, occurrence of angina pectoris, and the peak heart rate-blood pressure product (mm Hg × beats/min).

Statistical Analysis

The difference between pre- and postoperative exercise parameters was analyzed for statistical significance using Student's paired *t* test. The difference in the pre- and postoperative prevalence of ≥0.1 mV exercise-induced S-T segment depression and S-T segment depression plus angina pectoris was tested by chi-square analysis using contingency tables.

Results

Angiography: Four hundred thirty-five patients (420 men and 15 women) with a mean age of 48 years at the time of CABG were included in the study. Postoperative angiography was performed 8 weeks after surgery in 87 patients (20%) and 1 year after surgery in 348 patients (80%). Revascularization was complete in 182 patients, sufficient in 176, and incomplete in 57. Twenty patients had all grafts occluded. The mean number of

All values are mean ± 1 standard deviation. Numbers in parentheses represent number of patients examined.
All p values are comparisons with preoperative values: * $p < 0.0005$; † $p < 0.005$; ‡ $p < 0.05$; § not significant ($p > 0.05$).

diseased vessels, constructed anastomoses, patent distal anastomoses per patient, and the mean number of patent distal anastomoses per diseased vessel in the 4 groups are shown in Table I.

Exercise testing and follow-up: All patients had undergone exercise testing before and 1 year after CABG; most patients returned each year for routine exercise testing. For a mean follow-up time of 3.5 years, a mean number of 3.0 exercise tests per patient were available for review. The percentage of patients who returned at the indicated follow-up interval is shown in Table II. The results of preoperative and postoperative exercise testing in the 4 groups with respect to the different exercise variables are shown in Tables III to VI and Figure 1.

Exercise tolerance (Table III): Exercise tolerance was significantly increased 1 year after CABG in Groups I to III but not in Group IV. The gain in exercise tolerance was similar in Groups I and II 1 year after CABG but smaller in Group III. There was a slow but gradual decline of exercise tolerance with time: 4 years after CABG only the condition of patients in Groups I and II was improved and continued to improve up to 6 years, whereas patients in Group III failed to show significant improvement 4 to 6 years after surgery. Patients with all grafts occluded showed no significant improvement in exercise tolerance.

Angina-free exercise tolerance (angina threshold) (Table IV): The relief of angina pectoris after CABG was reflected in a higher exercise load that could be performed without the occurrence of angina. At 1 year after CABG, angina-free exercise tolerance was improved in all 4 subgroups; again patients in Groups I and II continued to have improved angina-free exercise tolerance up to 6 years after surgery, whereas in those in Groups III and IV the effect of CABG on exercise tolerance was no longer significant at 3 years and 2 years, respectively.

S-T segment depression (Table V): Before CABG >75% of patients had ≥0.1 mV S-T segment depression

TABLE V Prevalence of S-T Segment Depression During Exercise

Degree of Revascularization	Preoperative	Years Postoperatively 1	2	3	4	5	6
Complete	76 (138/182)	20* (36/182)	22* (34/155)	20* (25/125)	27* (30/113)	34* (21/61)	33* (16/49)
Sufficient	78 (137/176)	29* (52/176)	32* (44/135)	34* (40/116)	36* (33/92)	42* (14/33)	63 (14/22)
Incomplete	77 (44/57)	47† (27/57)	56‡ (25/45)	44† (17/39)	56§ (14/25)	43§ (3/7)	71§ (5/7)
All grafts occluded	85 (17/20)	35† (7/20)	21* (3/14)	17† (1/6)	50§ (3/6)	33‡ (2/6)	

Values represent percentages of patients with ≥0.1m S-T segment depression during exercise. Numbers in parentheses represent number of patients with S-T segment depression/number of patients examined.
All p values are comparisons with preoperative values: * $p < 0.0005$; † $p < 0.005$; ‡ $p < 0.05$; § not significant ($p > 0.05$).

TABLE VI Maximal Double Product (HR × mm Hg × min^{-1} × 10^{-2})

Degree of Revascularization	Preoperative	Years Postoperatively 1	2	3	4	5	6
Complete	193 ± 56 (182)	250 ± 71* (182)	259 ± 67* (155)	245 ± 75* (125)	241 ± 67* (113)	241 ± 70† (61)	236 ± 67‡ (49)
Sufficient	176 ± 47 (176)	235 ± 69* (176)	239 ± 63* (135)	241 ± 62* (116)	232 ± 57* (92)	219 ± 61† (33)	247 ± 75† (22)
Incomplete	186 ± 50 (57)	213 ± 53† (57)	219 ± 49† (45)	213 ± 45‡ (39)	202 ± 50§ (25)	199 ± 57§ (7)	226 ± 72§ (7)

All values are mm Hg × min^{-1} × 10^{-2} ± 1 standard deviation. Numbers in parentheses represent number of patients examined.
All p values are comparisons with preoperative values: * $p < 0.0005$; † $p < 0.005$; ‡ $p < 0.05$; § not significant ($p > 0.05$).

during exercise. Patients in all 4 groups improved after CABG; those who had undergone complete revascularization benefited most. Also, patients with all grafts occluded had less S-T segment depression after CABG. There was slow and progressive loss in improvement for all revascularization groups. Six years after surgery, only patients with complete revascularization had significantly less S-T segment depression than before surgery; also, the small number of patients with all grafts occluded had less S-T segment depression 5 years after surgery than before CABG.

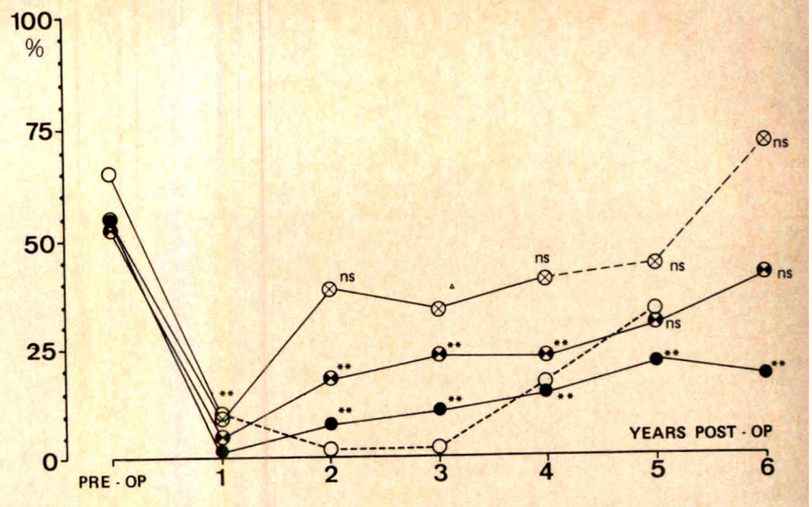
S-T segment depression and angina pectoris (Fig. 1): The occurrence of both S-T segment depression and angina pectoris during exercise testing can be considered a more reliable indicator of ischemia than either parameter alone.[9] All 4 groups benefited significantly with respect to the occurrence of angina pectoris and S-T segment depression at 1 year after CABG. At 2 years, in patients with incomplete revascularization, the prevalence of these combined parameters no longer differed from the prevalence before operation. Only patients with complete revascularization showed a highly significant lower prevalence of angina and S-T segment depression up to 6 years after CABG. The increase in prevalence of these combined parameters was 3% per year in patients with complete revascularization, approximately 6% in patients with sufficient revascularization, and approximately 10% in patients with incomplete revascularization.

Maximal double product (Table VI): The maximal product of heart rate and systolic blood pressure (maximal double product) that can be achieved during exercise correlates with myocardial oxygen supply during exercise.[10] The maximal double product achieved during exercise after CABG increased significantly in Groups I to III. The increase of the double product was similar in Groups I and II, and less marked in Group III. Patients with complete failure of the operation did not show a significant increase of the double product during exercise at 1 year after CABG. In Group III, the maximal double product was no longer improved at 4 years after surgery, whereas patients in Groups I and II showed significant improvement up to 6 years after surgery.

Analysis of all exercise parameters (Fig. 2): Patients with complete revascularization showed significant improvement in all 5 parameters up to 6 years after CABG (Fig. 2). Patients with sufficient revascularization showed significant improvement in all parameters up to 4 years after surgery, whereas those with incomplete revascularization showed improvement of all parameters only 1 year after CABG. Patients in whom there was complete failure of the operation showed improvement in only some exercise parameters at 1 year after surgery.

Discussion

In serial exercise testing improved exercise performance was demonstrated up to 1.5,[11] 2,[12] 3.5,[1] and 4 years[7] after CABG. Recently, improved exercise performance lasting up to 5 years after CABG was reported in a larger number of patients.[8] Postoperative angiographic evaluation of patients after CABG has demonstrated that the completeness of revascularization



DEGREE of REVASCULARIZATION							n = No. of exercised patients

FIGURE 1. Prevalence of exercise-induced angina pectoris in combination with exercise-induced S-T segment depression in the 4 groups before and 1 to 6 years after CABG. All groups were improved 1 year after CABG; the annual recurrence rate of this combined parameter is 3% for patients with complete revascularization, 6% for those with sufficient revascularization, and approximately 10% for those with incomplete revascularization. Only patients with complete revascularization showed significant improvement up to 6 years postoperatively (POST-OP). All p values compared with preoperative (PRE-OP) results. gr. occl. = graft occlusion; ns = not significant.

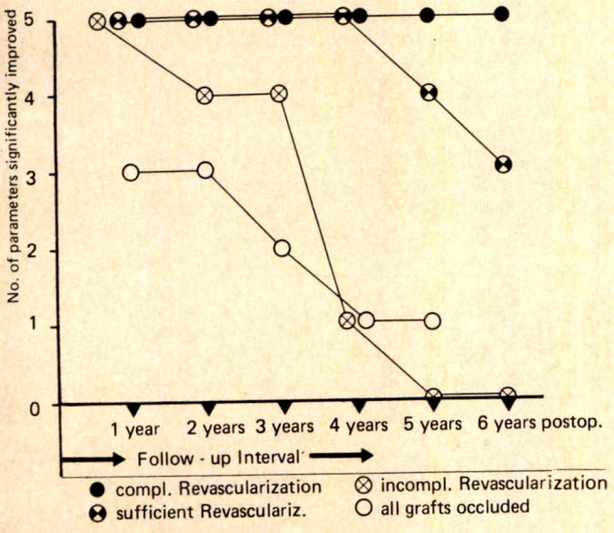

FIGURE 2. Summary of results of Tables III to VI and Figure 1. Illustrated are the number of examined parameters that were significantly improved at 1 to 6 years after surgery in comparison with preoperative parameters. Only patients with complete (compl.) revascularization had improvement in all exercise parameters up to 6 years after surgery. Exercise parameters examined were exercise tolerance, angina-free exercise tolerance (angina threshold), prevalence of ≥0.1 mV S-T segment depression, prevalence of S-T segment depression plus angina pectoris, and maximal double product of heart rate and systolic blood pressure.

correlates with the degree of symptomatic improvement as evaluated by the classification of the New York Heart Association and also with the extent of early[4,13] and late[14,15] functional improvement after CABG as well as with improvement in exercise hemodynamic variables.[16] Siegel et al[13] reported on 128 patients who underwent postoperative angiographic evaluation between 2 and 29 months after CABG. Eleven patients with partial or complete graft failure had no significant improvement in most exercise parameters, whereas patients with complete revascularization had significant improvement in all exercise parameters 2 to 29 months after CABG. Lawrie et al[15] reexamined 51 patients more than 5 years after CABG with angiographic reevaluation and noted a better exercise performance with respect to the occurrence of chest pain, S-T segment depression, exercise duration, maximal heart rate, and maximal double product in patients who had no residual lesions compared with those who had 1 or 2 residual lesions. However, no preoperative comparisons were available and no statistical analysis was performed. There are, however, no prospective data available on the duration of functional improvement measured with exercise testing in angiographically defined subsets of patients with different degrees of revascularization.

Most of the studies dealing with the long-term effect of CABG on improvement in functional class or in exercise tolerance were performed in patients operated on in the early 1970s with mostly incomplete revascularization and a lower graft patency rate than that accomplished in recent years. Therefore, results after CABG obtained today may be superior to those obtained in the early 1970s.[17] The prevalence of S-T segment depression with angina pectoris at low levels of exercise (≤50 W) was recently reported to be as low as 10% at 5 years after CABG.[18]

Our results indicate that patients with complete revascularization—as determined by postoperative angiography—had an excellent result with respect to all examined parameters at 1 year after surgery. This is in agreement with previous reports.[1,13,14] The improvement in the parameters of exercise performance is maintained up to 6 years after CABG. Thus, although CABG is a palliative procedure, there was only slow loss in improvement over the years, and the new occurrence

of S-T segment depression with exercise-induced angina was approximately 3% per year in this subgroup. The occurrence of new symptoms can be attributed to a graft occlusion rate of 2% per year after the first year and to progression of disease in the native coronary arteries.[19–21] Because sequential angiography was not performed, the contribution of each individual component cannot be assessed in these patients.

Patients with sufficient revascularization also had significant improvement in all exercise parameters at 1 year after CABG (to a slightly lesser extent than in the group with complete revascularization). Furthermore, the improvement in all exercise parameters lasted only up to 4 years after CABG.

At 5 years the prevalence of exercise-induced angina pectoris combined with S-T segment depression was no longer different from the preoperative prevalence; however, the angina-free exercise tolerance (angina threshold) was still significantly greater than before CABG. Thus, despite a similar occurrence of S-T segment depression associated with angina pectoris at 5 years after surgery, this group was able to perform a greater work load without occurrence of angina pectoris than before surgery, and therefore still had significant benefit from the operation. This example illustrates that it is necessary to consider more than only a single parameter (that is, S-T segment depression) in the evaluation of postoperative exercise testing.

In Group III the 1-year postoperative improvement of exercise performance was markedly less than in patients with complete revascularization: The exercise tolerance, the angina-free exercise tolerance, and the maximal double product were significantly lower than in the group with complete revascularization. The steep increase in the prevalence of S-T depression plus angina between 1 and 2 years might be explained by partial denervation at 1 year, because the prevalence of S-T depression is high but patients do not experience angina.

Patients with all grafts occluded showed improvement in only some parameters 1 year after CABG. Remarkable is the absence of angina and S-T segment depression during exercise. However, exercise tolerance and maximal double product were not improved. Similar results were reported by Block et al[22] in patients who underwent unsuccessful revascularization.

In conclusion, in our study correlations between angiographically defined degrees of revascularization and the long-term effect of CABG on exercise performance could be demonstrated. The long-term outlook for patients in whom complete revascularization has been achieved is excellent. Patients with lesser degrees of revascularization have not only less improvement after surgery, but also a higher rate of recurrence of symptoms during the follow-up years.

Limitations of the study: Although the mean number of grafts placed in the patients included in this study is smaller than the number of grafts placed today in our institution, the assessment of the degree of revascularization achieved during surgery has not changed much during recent years. A major change has taken place in patient selection: patients who would have been denied surgery at the time of this study can undergo successful CABG today with up to 8 and more distal anastomoses by sequential graft technique.[23] However, long-term results in patients with multiple distal anastomoses by sequential graft technique are still pending.

Cardiokymography During Exercise Testing: A New Device For the Detection of Coronary Artery Disease and Left Ventricular Wall Motion Abnormalities

DONALD A. WEINER, MD, CAROLYN H. McCABE, BS, GINA DAGOSTINO, BS, SALLY S. CUTLER, BS, and THOMAS J. RYAN, MD

The cardiokymograph (CKG) is a device that has been shown to reflect left ventricular (LV) wall motion abnormalities. Its accuracy in detecting coronary artery disease (CAD) during treadmill exercise testing was assessed in 204 consecutive patients undergoing coronary arteriography. Of the 188 patients with a technically adequate CKG, 146 (78%) had significant CAD. The sensitivity and specificity were similar for both the exercise electrocardiogram (ECG) (66% and 86%, respectively) and the exercise CKG (73% and 95%, respectively). An abnormal exercise CKG was significantly more common in patients with 3-vessel CAD than in those with 1-vessel disease (97% versus 52%, respectively; p <0.001) and in patients with left anterior descending disease than in those without (85% versus 26%, respectively; p <0.001). Seventy patients showed both an abnormal exercise ECG and CKG; all had CAD and 86% had multivessel CAD. Forty-eight patients demonstrated a normal exercise ECG and CKG; 29% had CAD but only 6% had multivessel CAD. Among 55 patients who had simultaneous exercise radionuclide ventriculography, new septal or apical wall motion abnormalities were found in 79% (23 of 29) of patients with an abnormal CKG compared with 19% (5 of 26) of patients with a normal CKG (p <0.001). Thus, the CKG during exercise testing accurately reflects LV wall motion abnormalities and can be used to improve the diagnostic accuracy of exercise testing as an additional marker of myocardial ischemia.

The diagnosis of coronary artery disease (CAD) may be difficult to ascertain on the basis of the history, physical examination, and resting electrocardiogram (ECG). Even the standard exercise test has diagnostic limitations for the detection of CAD because of poor sensitivity or specificity in different population groups.[1–3] For these reasons, other noninvasive tests have been used to aid in the diagnostic evaluation of CAD, such as exercise thallium[4,5] or radionuclide ventriculography[6,7]; however, these studies are expensive, require complex equipment, and entail the risk, albeit small, of radiation exposure.

The cardiokymograph (CKG) offers an additional independent marker of myocardial ischemia.[8–11] It is a relatively simple device that has been shown experimentally to accurately detect regional wall motion by recording tissue movements through changes in an electromagnetic field, and it can be recorded at rest and shortly after exercise. In 1 previous clinical study by the investigators who initially described the device,[12] the sensitivity and specificity of the exercise CKG was significantly better than that obtained with exercise ECG.[13] This investigation further analyzes the diagnostic accuracy of the CKG performed in conjunction with exercise testing. A subgroup of patients additionally underwent exercise radionuclide ventriculography to correlate left ventricular (LV) wall motion during exercise recorded by the CKG with that detected by radionuclide ventriculography.

Methods

Patients: During an 18 month period, 204 consecutive patients (175 men and 29 women) with a mean age of 53 ± 7 years (range 31 to 75) without prior cardiac surgery were referred for cardiac catheterization because of suspected or known CAD and were able to undergo exercise testing. The decision to perform cardiac catheterization was made by the patient's attending physician before the exercise test which was performed 1 day before catheterization. The chest pain com-

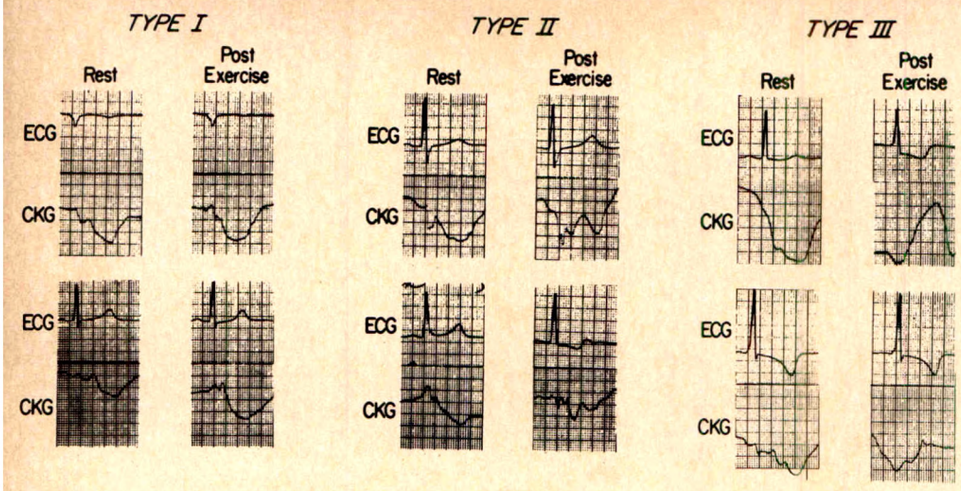

FIGURE 1. Two examples each of the 3 types of cardiokymographic patterns at rest and 2 to 3 minutes after exercise: Type I, the normal response, demonstrated inward systolic motion; Type II, an abnormal response, consisted of a paradoxical outward systolic movement postexercise after an initial early inward motion; and Type III, an abnormal response, exhibited total outward systolic motion postexercise. CKG = cardiokymography; ECG = electrocardiography.

plaints of the patients were categorized into 1 of 3 groups before catheterization: typical angina (64%), atypical angina (19%), and nonischemic chest pain (12%). Six percent of the patients were asymptomatic after a myocardial infarction.

Cardiokymography: Each patient had a CKG at rest and during recovery from exercise. The electronic features of the CKG have been previously described in detail.[8–14] In brief, the CKG (Cardiokinetics, Seattle, Washington) consists of a circular, flat capacitive plate which is mounted in a plastic ring and strapped to the chest. Tissue motion beneath the plate distorts an induced electromagnetic field which in turn alters the frequency of an external oscillator. This change in frequency is converted into a change in voltage proportional to the original motion, which is then amplified and displayed on a multichannel recorder as a continuous analog signal. The frequency response of the system is flat ±10% from 0.1 to 90 Hz.[14]

The CKG tracing was initially recorded in the supine position at end-expiration with the ring placed over the precordium between ECG positions V_2 to V_5, and a transthoracic ECG lead was recorded simultaneously at a paper speed of 50 mm/s. The optimal position for the most accurate CKG tracing was marked on the chest (most commonly obtained in the V_3 position). Within 2 to 3 minutes after cessation of exercise, a CKG tracing was again obtained using the same position at end-expiration as previously recorded at rest, and was then repeated at least once more during the recovery period.

The CKG tracings were interpreted by 3 independent readers who had no prior knowledge of the results of the exercise ECG or coronary arteriogram. Two readers interpreted all the CKG tracings on separate occasions, at least 2 weeks apart. The tracings were classified according to 3 patterns (Fig. 1) as previously described by Silverberg et al[13]: *Type I*, the normal pattern, was characterized by an initial upward systolic preejection movement followed by a downward motion during ejection, representing inward motion of the LV wall. The *Type II* pattern consisted of a paradoxical systolic outward motion with an amplitude ≥50% of the initial inward motion during early systole. *Type III* motion demonstrated total outward motion during systole without any inward motion. The CKG tracings were considered abnormal if a Type I motion at rest became Type II or III after exercise or a Type II response at rest became Type III after exercise and then returned to the control tracing during recovery.

Exercise test: All patients underwent a symptom-limited, maximal treadmill exercise test according to the standard Bruce protocol.[15] A 12-lead ECG and blood pressure were recorded at rest and during each stage of exercise and recovery. An abnormal electrocardiographic response was defined as the appearance of 1 mm of horizontal or downsloping S-T segment depression or 1.5 mm of upsloping S-T segment depression 80 ms after the J point for 3 consecutive beats during exercise or recovery compared with the upright tracing. If the resting ECG showed S-T segment depression, an additional 1 mm of depression was required.

Exercise radionuclide ventriculography: Fifty-five patients, randomly selected, underwent supine exercise radionuclide ventriculography on the same day as the treadmill exercise test. Radionuclide ventriculography was performed after labelling of red blood cells with technetium-99 sodium pertechnetate according to the technique previously described.[6]

Regional LV function was assessed by analysis of wall motion using both the cinematic display of the average cycle and the static display of the superimposed end-diastolic and end-systolic perimeters. Wall motion was categorized either as normal, hypokinetic, akinetic, or dyskinetic. Abnormal wall motion during exercise was defined as a new hypokinetic, akinetic, or dyskinetic motion involving the apical or septal walls. If the wall motion was abnormal at rest, a positive exercise response consisted of worsening of these abnormalities (hypokinetic to akinetic or akinetic to dyskinetic).

Coronary arteriography: Selective coronary arteriograms using the brachial or femoral techniques were recorded in multiple projections. Significant CAD was judged present if ≥50% reduction in vessel diameter occurred in the left main coronary artery or a ≥70% narrowing was present in ≥1 of the other major arterial segments. Of the 204 patients, 78% had significant CAD. One-, 2-, and 3-vessel disease was found in 57 patients (28%), 63 patients (31%), and 39 patients (19%), respectively.

Statistical analysis: All analyses of data were performed using chi-square analysis with Fisher's exact test utilized for small sample sizes. Probabilities were considered significant at the 0.05 level.

Results

Technically adequate CKG tracings were obtained in 92% of the 204 patients. Among the 16 patients with inadequate tracings, 12 had a history of myocardial infarction, 11 were classified as having typical angina, and 8 had multivessel CAD.

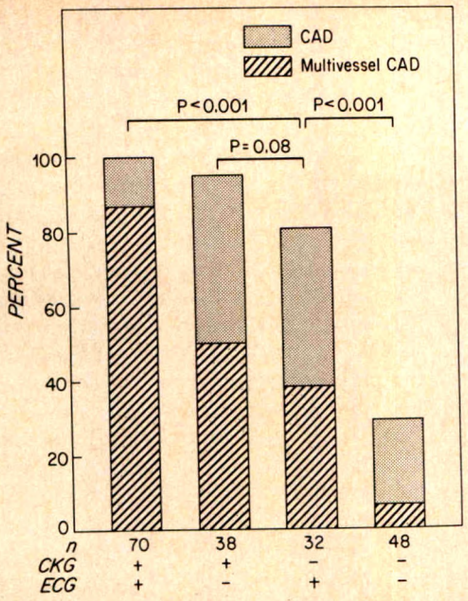

FIGURE 2. Correlation between the combined stress test cardiokymographic and electrocardiographic results and the presence of CAD and multivessel disease. CAD = coronary artery disease; CKG = cardiokymography; ECG = electrocardiography.

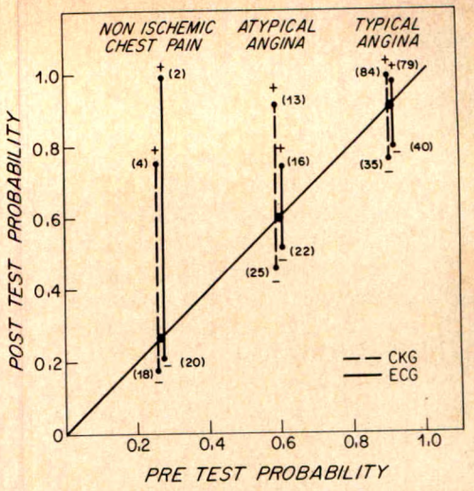

FIGURE 3. The probability of coronary artery disease before and after a positive or negative cardiokymographic (**dashed lines**) or electrocardiographic (**solid lines**) response. The **numbers in parentheses** refer to the number of patients with a given test result in the specific symptomatic subgroup listed at top of the figure. CKG = cardiokymography; ECG = electrocardiography.

Inter- and intraobserver variability: All 3 readers of the CKG tracings were in complete agreement 78% of the time. The discordant interpretations were resolved by group review. Intraobserver variability was found in 9% of the interpretations by 1 reader and 8% by the second reader.

Sensitivity and specificity: Of the 188 patients with technically adequate CKG tracings, 146 (78%) had significant CAD. The CKG stress test was abnormal in 106 patients (sensitivity 73%) while the ECG stress test was abnormal in 96 patients (sensitivity 66%, p not significant [NS]). There were 56 Type II responses and 50 Type III responses after exercise among the 106 abnormal CKG tracings. Either an abnormal CKG or ECG stress test response was present in 90% of the patients ($p < 0.001$, compared with the sensitivity of either the ECG or CKG test alone). In the 14 patients with CAD, whose CKG and ECG stress tests were normal, 10 (71%) failed to reach at least 85% of the age-predicted maximum heart rate, and 11 (79%) had single-vessel CAD.

Of the 188 patients, 42 (22%) had no significant CAD. The CKG stress test was negative in 40 patients (specificity 95%), the ECG stress test was negative in 36 patients (specificity 86%, p = NS), and both stress tests were negative in 34 patients (specificity 81%). Both patients with false-positive CKG stress tests had Type II responses.

Influence of the extent and distribution of CAD: The CKG stress test was abnormal in 52% of patients with 1-vessel CAD, 76% of patients with 2-vessel CAD, and 97% of patients with 3-vessel CAD ($p < 0.001$). The stress test CKG was more sensitive in detecting patients with 3-vessel CAD than was the ECG (97% versus 78%, respectively; $p < 0.01$).

One-hundred patients had significant disease of the left anterior descending coronary artery. The CKG was abnormal in 85% of these patients, compared with 26% of the 88 patients without significant left anterior descending coronary narrowing ($p < 0.001$).

Correlation between the combined test results and CAD (Fig. 2): One-hundred eighteen patients (63%) had concordant results for the CKG and ECG stress tests (70 positive, 48 negative). CAD and multivessel disease were present in 100 and 86%, respectively, of the patients with concordantly positive results compared with 29 and 6%, respectively, of the patients

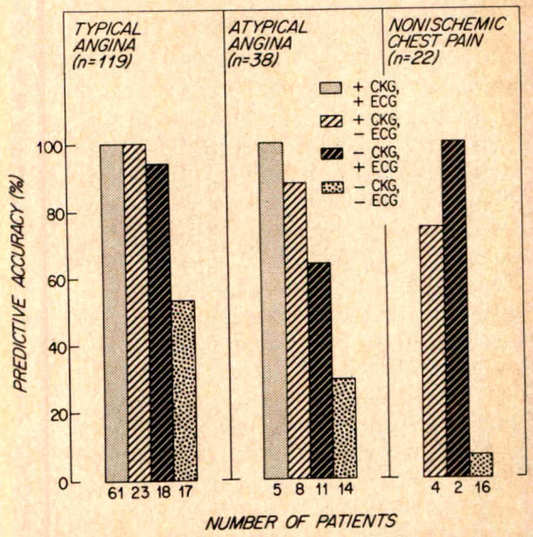

FIGURE 4. Predictive accuracy of concordant or discordant test results in patient subgroups according to symptomatic status. CKG = cardiokymography; ECG = electrocardiography.

with concordantly negative results ($p < 0.001$). When the results of the 2 stress tests were discordant, 62 (89%) of the 70 patients had CAD, and multivessel disease was present in 44%. The predictive accuracy of discordant results for CAD was slightly but not significantly greater for a positive CKG response than for a positive ECG result (95 versus 81%, respectively; $p = 0.08$).

Influence of symptoms and disease prevalence on the accuracy of individual (Fig. 3) and combined (Fig. 4) test results: A history of typical angina pectoris was highly predictive (92%) of the presence of significant CAD. A positive CKG response slightly increased (100%) the probability of CAD. A negative test result, however, was still associated with a high likelihood of CAD in this group of patients (80% for the ECG, 74% for the CKG [Fig. 3], and 53% for concordantly negative tests [Fig. 4]).

In the group classified as having atypical angina, 23 of the 38 patients (60%) were found to have significant CAD. The likelihood of having CAD increased to 92% when the CKG stress test was abnormal (Fig. 3) and 100% when both tests were abnormal. Concordantly negative results were associated with a 29% probability of CAD but only a 7% probability of multivessel disease (Fig. 4).

In the group with nonischemic chest pain, 6 of the 22 patients (27%) had CAD. Six of the patients had either an abnormal CKG or ECG stress test and 1 of the 6 had a false-positive result. Only 1 (6%) of 16 patients with concordantly negative results had CAD in 1 vessel (Fig. 4).

Correlation between cardiokymographic stress test and exercise radionuclide ventriculography: Of the 55 patients tested, 25 had new septal or apical wall motion abnormalities during exercise radionuclide ventriculography and 3 had worsening of preexisting abnormalities. These abnormalities were seen more frequently in the patients with an abnormal CKG stress test (79%, 23 of 29) than in those with negative CKG stress tests (19%, 5 of 26; $p < 0.001$).

Discussion

This study confirms the findings of the 1 previous clinical investigation that stress test cardiokymography is a useful method for detecting myocardial ischemia.[13] The sensitivity and specificity in this consecutive series of patients referred for cardiac catheterization were slightly better than that of exercise electrocardiography and comparable to the results in previous studies analyzing stress test thallium[4,5] or exercise radionuclide ventriculography.[16,17] Its relative simplicity and lack of radiation risk, moreover, makes the CKG an attractive addition to be used in conjunction with the standard exercise test for diagnostic evaluation.

The CKG has been shown experimentally to detect regional wall motion abnormalities[11] which often occur as the initial manifestation of CAD[18] preceding either metabolic[19] or ECG S-T segment abnormalities.[20] This investigation confirms these experimental findings by illustrating that most (79%) patients with abnormal CKG stress tests also demonstrate abnormal LV contraction patterns as determined by exercise radionuclide ventriculography. Since the left anterior descending coronary artery supplies the major portion of the anterior wall, it is not surprising that 85% of patients with abnormal CKG stress tests also had significant left anterior descending narrowing.

Myocardial ischemia during exercise may cause either electrical or mechanical abnormalities. Since the exercise ECG and CKG may detect these different manifestations, analysis of the combined test results should enhance the diagnostic accuracy of either test result alone. When concordantly positive test results were observed, 100% of patients were correctly identified as having CAD, and in 86%, multivessel disease was found. Although concordantly negative results did not entirely eliminate the probability of CAD (29%), the likelihood of finding multivessel disease was extremely low (6%). Two points regarding the 29% prevalence of false-negative responses should be emphasized. First, 10 of the 14 patients with concordantly negative results did not achieve 85% of the maximally predicted heart rate. If these patients were eliminated, only 8% of concordantly negative responders had CAD. Second, our patient population was referred for cardiac catheterization and had a high pretest risk of CAD (78%). In other groups of patients with a lower pretest risk, concordantly negative results would likely yield a lower post-test likelihood of CAD.

Recent studies have emphasized that the results of any noninvasive test used for the detection of CAD depend not only on the sensitivity and specificity of the test result but also on the pretest likelihood of disease in the patient group tested according to Bayesian theorem.[3,21–23] Our investigation supports these conclusions. In the patients with a history of typical angina, a positive stress test ECG or CKG only slightly increased a high pretest risk. Negative combined test results would likely indicate 0- (47%) or 1-vessel (41%) CAD. In the patients with atypical chest pain (the groups classified as having either atypical angina or nonischemic chest pain), a positive CKG stress test alone raised the probability of CAD from 48 to 88%. If both test results were negative, the likelihood of CAD was 17%, with only 1 patient (3%) having multivessel CAD. The CKG stress test as a diagnostic device appears most helpful in patients with atypical symptoms and intermediate pretest risk of CAD.

The inter- and intraobserver variability of CKG interpretations was comparable to that reported for thallium scanning without computer assistance.[24–26] Inadequate tracings were obtained in 8% of the group, a figure that is dependent on the experience and patience of the operator. Although technically adequate exercise ECG tracings were obtained in all patients, the ECG response may be uninterpretable in the presence of a left bundle branch block or LV hypertrophy on the resting ECG or in the patient taking digitalis preparations. In these patients, the CKG stress test may be helpful.[13]

Although the results of the present study were based upon a consecutive series of patients, the population was selected for cardiac catheterization and thus had a high prevalence of CAD. Our conclusions might not be ap-

plicable to other symptomatic patients not undergoing catheterization or to asymptomatic subjects whose pretest risk of CAD would be lower.

In summary, the results of the present investigation establish the CKG stress test as a useful noninvasive technique for the detection of CAD. It can be performed in conjunction with the standard exercise electrocardiogram to provide additional diagnostic information as an independent marker for myocardial ischemia.

Rest and Redistribution Thallium-201 Myocardial Scintigraphy to Predict Improvement in Left Ventricular Function After Coronary Arterial Bypass Grafting

ABDULMASSIH S. ISKANDRIAN, MD, A-HAMID HAKKI, MD, SALLY A. KANE, RN, INDER P. GOEL, MD, ELDRED D. MUNDTH, MD, A-HADI HAKKI, MD, and BERNARD L. SEGAL, MD, *With the technical assistance of* ANGELO AMENTA, NMT

To examine the value of rest and redistribution thallium-201 imaging in predicting improvement in left ventricular (LV) ejection fraction (EF) after coronary artery bypass grafting (CABG), 26 patients with coronary artery disease (CAD) and abnormal LV function were studied. Nineteen patients had pathologic Q waves preoperatively. Rest and redistribution thallium-201 images and radionuclide ventriculograms were obtained before and after CABG, and the thallium scintigrams were evaluated both quantitatively and qualitatively. The patients were divided according to the preoperative thallium scintigrams into 2 groups: Group I (16 patients) had either normal resting thallium-201 images or reversible resting perfusion defects, and Group II (10 patients) had fixed resting perfusion defects. The resting EF was <50% preoperatively in all patients. Fourteen patients (54%) showed improvement in EF postoperatively. Three patients (2 in Group I and 1 in Group II) showed new postoperative perfusion defects, and none of the 3 showed improvement in LV function. Of the remaining 14 patients in Group I, 12 (86%) showed improvement in LV function, compared with 2 of 9 patients in Group II ($p < 0.01$). Improvement in LV function was observed in 8 of the 19 patients (42%) with abnormal Q waves. Nitroglycerin intervention radionuclide ventriculograms were obtained in 20 patients before CABG. Of the 6 patients who showed improvement in LV function with nitroglycerin, 4 also showed improvement postoperatively. Postoperative improvement in LV function was also observed in 6 of the 14 patients who did not improve with nitroglycerin.

Thus, rest and redistribution thallium imaging is useful in identifying patients whose LV function will improve after CABG. Normal rest thallium-201 images or reversible resting defects correctly identified 12 of 14 patients (86%) who showed improvement in LV function postoperatively. Nitroglycerin-intervention ventriculography and abnormal Q waves were less useful in this differentiation.

Thallium-201 myocardial perfusion imaging has been found to be a useful diagnostic test for coronary artery disease (CAD).[1] The pharmacokinetic features of thallium-201 have been well studied in humans and in nonhumans.[2,3] The delayed or redistribution images reflect the cellular and enzymatic integrity of the myocardium. Normalization of defects present in the postexercise images has been taken as evidence of cellular viability. In this study, we evaluated the potential use of rest and redistribution thallium-201 scintigraphy to predict improvement in global left ventricular (LV) function after coronary artery bypass grafting (CABG).

Methods

Patients: The patient population consisted of 26 patients: 22 men and 4 women aged 41 to 69 years (mean 59). These patients had severe but stable patterns of angina pectoris and were identified after cardiac catheterization because all had (1) severe CAD defined as ≥70% diameter narrowing of 1 or more major vessels, (2) abnormal LV ejection fraction (EF) by contrast left ventriculography (<50%), and (3) underwent CABG.

These patients were consecutive patients in whom radionuclide angiographic and perfusion studies were available pre- and postoperatively. Because of the severity of symptoms, exercise studies were not performed. Four additional patients were excluded because they died in the perioperative period and thus postoperative studies were not available. All 4 patients had very poor LV function and large fixed perfusion defects consistent with scar.

Patients with preoperative LV EF ≥50% were excluded because improvement in LV function is not expected in these patients after CABG. Also, patients with LV aneurysms that required resection were excluded. No patient had had recent myocardial infarction (within 3 months before the study) and none required concomitant valve replacement (Table I).

The highest levels of enzymes during the first 3 postoperative days are shown. X is the upper limit of normal in our laboratory for creatine phosphokinase. * = abnormal washout by circumferential radial activity analysis; — = not done.

AL = anterolateral; AMI = anterior myocardial infarction; Ap = apex; CAD = coronary artery disease; CPK = creatine phosphokinase; ECG = electrocardiographic; EF = ejection fraction; Inf = inferior; IMI = inferior myocardial infarction; IVCD = intraventricular conduction delay; CPK-MB = isoenzyme of creatine phosphokinase; LBBB = left bundle branch block; NG = nitroglycerin; NL = normal; #VD = number of vessel disease; PD = perfusion defect; Pos = posterior; Postop = postoperative; Preop = preoperative; Pt = patient; RBBB = right bundle branch block; Sep = septum; ST-T = ST segment and T-wave abnormalities.

CABG was performed utilizing the autogenous reversed saphenous vein in each patient with use of moderate systemic hypothermia and potassium cardioplegia. One to 3 days before the operation, each patient underwent thallium-201 imaging and radionuclide ventriculography. These studies were repeated 7 to 10 days postoperatively.

Radionuclide ventriculograms were obtained using the first-pass method with a multicrystal gamma camera (Baird-Atomic System-77).[4] Radionuclide ventriculography was repeated in 20 patients after sublingual administration of nitroglycerin, administered until there was ≥10% decrease in systolic blood pressure or a 10% increase in heart rate.

Thallium-201 myocardial scintigraphy: Myocardial scintigrams were obtained at rest in all patients after an overnight fast following intravenous injection of 2 mCi of thallium-201. Delayed (or redistribution) images were repeated after 4 hours in the same projections. In 11 patients, the pre- and postoperative images were obtained with the multicrystal camera. The technique for imaging and processing has been described in detail elsewhere.[5,6] In the remaining 15 patients, pre- and postoperative images were obtained with an Ohio Nuclear Series 420 mobile scintillation camera equipped with a low-energy, all-purpose, parallel-hole collimator. The images were subjected to 9-point weighted smoothing and interpolative background subtraction by the method described in detail elsewhere.[7] Circumferential profiles were obtained from the rest and redistribution images. A computer-generated circumference was constructed around the outer edge of the left ventricle, and radii were then constructed by the computer from the image-center to each point on the circumference, each radius being separated from the others by 6°. The average activity per pixel along the radius was calculated. A curve representing the normalized thallium activity versus the angular location was described starting from the radius, oriented at 3 o'clock, and proceeding counterclockwise. The rest and redistribution curves were aligned and displayed together.[7]

Redistribution was considered to have occurred when there was "filling in" of the defects, which in most cases was due to slower washout from the abnormal segment compared with the normal segment. Less commonly, the activity profile showed another pattern characterized by higher activity in the redistribution image compared with the same segment in the initial images. The abnormal washout was often associated with visually apparent filling in of the perfusion defects that were present in the initial images. Occasionally, however, this pattern of abnormal washout was seen in a segment that subjectively was interpreted as normal.

Finally, the images in the anterior and the left anterior oblique projections from both the rest and the redistribution studies were each divided into 5 segments. The activity in each segment was graded as follows: 4+, normal; 3+, mildly decreased; 2+, moderately (but definitely) decreased; 1+, severely decreased; or 0, absent.

The thallium images were interpreted randomly by 2 observers without knowledge of which scans were preoperative and which were postoperative and without knowledge of other test results. There were no major disagreements between the

2 observers related to the presence or absence of perfusion defects. Minor disagreements related to the scoring of the defects or to the extent of the defects were resolved by discussion.

Electrocardiograms and isoenzyme studies were obtained for at least the first 3 days after the operation to determine the presence or absence of perioperative infarction. Seven to 10 days after the operation a rest radionuclide ventriculogram and rest thallium-201 scintigram were obtained as described. Because the radionuclide ventriculograms were obtained in 1 projection (anterior), which enables evaluation of wall motion in only 3 segments, evaluation of wall motion is not discussed in this study.

Postoperative improvement in LV function was defined as ≥5% increase in EF compared with the control measurement obtained preoperatively.

Statistical analysis: Statistical analysis was performed with the *t* test and the chi-square test. A p value <0.05 was considered statistically significant.

Results

One patient had 1-vessel disease, 6 patients had 2-vessel disease, and 19 patients had 3-vessel disease (Table I). The resting electrocardiograms showed previous transmural infarction in 19 patients. The cardiac enzymes did not appear useful in the diagnosis of perioperative infarction. There was no significant change in end-diastolic volume (measured by radionuclide angiography) after CABG (246 ± 73 ml preoperatively versus 236 ± 72 ml postoperatively; difference not significant). Similarly, there was no significant change in the systolic blood pressure; however, the heart rate was significantly higher after CABG (66 ± 9 beats/min preoperatively versus 85 ± 12 beats/min postoperatively; $p<0.001$), probably because many patients were not receiving propranolol after CABG.

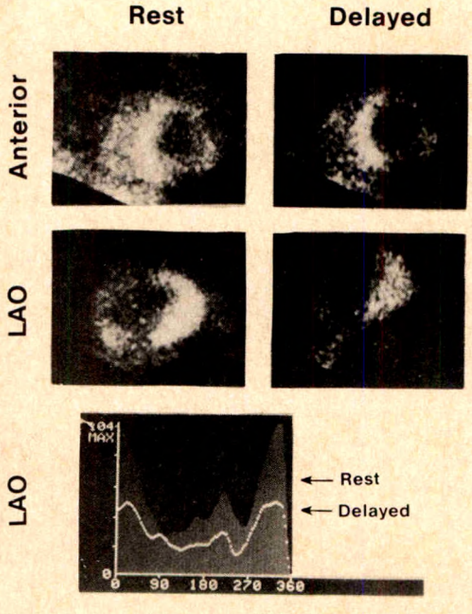

FIGURE 1. Rest and delayed thallium-201 images in a patient with 3-vessel disease. The scans are abnormal, showing fixed defects. The circumferential profile analysis in the initial and delayed images in the left anterior oblique (LAO) projection is also shown.

Thallium-201 myocardial scintigrams: Resting perfusion defects were present in 20 of the 26 patients (77%) (Table I). Qualitative analysis showed reversible defects in 6 patients and fixed defects in 14 patients. An abnormal washout was present in 4 of the 14 patients with fixed defects. The abnormal washout was detected in segments with apparently normal perfusion patterns. All such areas were, however, subserved by severely stenotic coronary vessels. The remaining 10 patients had only fixed defects (Fig. 1). Furthermore, 1 of the 6 patients with normal resting scans had an abnormal washout, indicating the presence of global hypoperfusion. Therefore, a total of 11 (42%) of the 26 patients had redistribution in the delayed images.

Comparison of pre- and postoperative studies: The patients were divided into 2 groups. Group I patients had either normal resting scans or reversible perfusion defects (16 patients); Group II patients (10) had fixed defects only (Table I, Fig. 3 and 4).

Four of the 6 patients with normal scans had improvement in EF after CABG. A new perfusion defect was detected postoperatively in 1 of the 2 patients who did not show such improvement (Patient 2; Table I, Fig. 3 to 5).

In 8 of 10 patients with reversible perfusion defects, there was improvement in the thallium images (Fig. 2 and 4) and improvement in LV EF after CABG (Fig. 3 and 5). The remaining 2 patients (9 and 10, Table I) showed no improvement in LV EF and 1 of the 2 patients showed new perfusion defects postoperatively (Patient 10).

In Group II, 7 of 10 patients had no change in EF postoperatively. Two patients had improvement in EF but no change in thallium images (Patients 17 and 18; Table I, Fig. 3 to 5). One patient had a lower thallium score and a new perfusion defect postoperatively (Patient 26, Table I). Most patients who showed improvement in thallium scans in the delayed and postoperative studies had initial thallium scores between 20 and 26.

If the 3 patients with the new appearance of defects are excluded, then 12 of the 14 patients (86%) in Group I had improvement in EF after CABG, compared with 2 of 9 patients in Group II ($p<0.01$).

Thus, 14 of the 26 patients (54%) showed improvement in global LV EF postoperatively (Fig. 5), and the

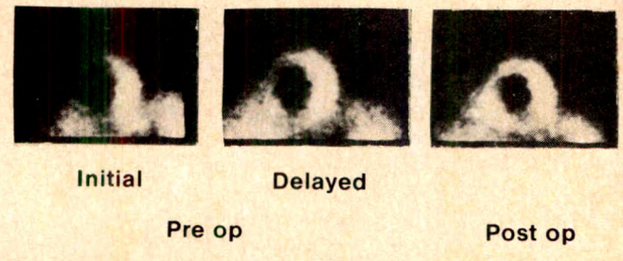

FIGURE 2. Rest thallium-201 images in the 30° left anterior oblique projection before and after coronary artery bypass surgery. The preoperative (Preop) image shows a large defect involving the septum and inferoapical segment. The postoperative (Postop) image shows improvement of perfusion. The delayed preoperative study showed partial redistribution.

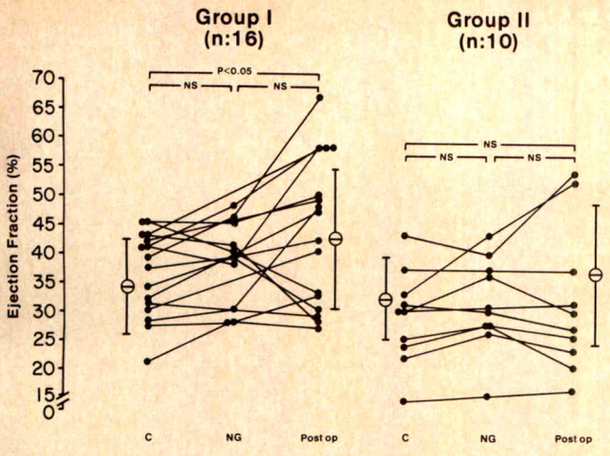

FIGURE 3. Left ventricular ejection fraction in the control state (C), after nitroglycerin (NG), and after operation (Postop). Means ± standard deviation are also shown. n = number of patients; NS = not significant.

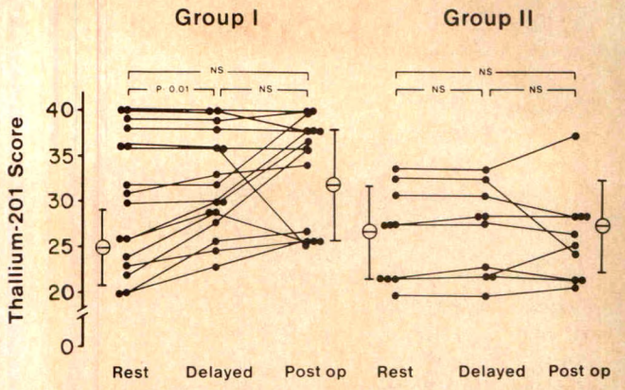

FIGURE 4. Total thallium scores before (rest and delayed) and after surgery (Postop). Means ± standard deviations are also shown. NS = not significant.

change in EF was correctly predicted in 83% of the patients. Eight (42%) of the 19 patients with previous transmural infarction showed improvement in LV EF postoperatively.

Nitroglycerin-intervention ventriculograms: In 20 patients for whom nitroglycerin-intervention radionuclide ventriculograms were available, 6 showed improvement in EF with nitroglycerin (≥5% increase in EF). The rather low percentage of improvement with nitroglycerin is probably because many patients had prior infarction. Of those, 4 showed improvement in EF after CABG. On the other hand, of the remaining 14 patients who showed no improvement in EF with nitroglycerin, 6 patients (43%) had improvement in the EF postoperatively. Thus, nitroglycerin radionuclide ventriculograms predicted the correct change in only 12 of the 20 patients (60%) (Fig. 5).

The predictive value of thallium scintigraphy (83%) was higher than that of nitroglycerin radionuclide ventriculograms (60%), or that of the abnormal Q waves (42%).

Discussion

In this study, we found areas with transient resting hypoperfusion by means of rest thallium-201 images in 11 of the 26 patients (42%). The reversible perfusion abnormalities were seen in the absence of clinically evident episodes of myocardial ischemia. This finding is consistent with those in other reports.[8,9]

Changes in LV function after CABG have been extensively studied, but the results have been conflicting.[10–23] The reasons for these disparate results may be traced to several factors: First, patients with normal LV function preoperatively are unlikely to have improvement in function postoperatively. Second, the presence of perioperative infarction may cause deterioration in LV function postoperatively. However, early investigators did not utilize technetium-99m pyrophosphate studies, which have been shown to increase reliability in detecting perioperative infarction.[24–27] Depression of LV function may also be due to myocardial ischemia and injury during cardioplegic arrest.[28] Third, improvement in segmental asynergy may occur with no obvious change in global LV function.[29]

In this study, we found that patients with abnormal LV function may have a normal resting perfusion pattern, reversible defects, or fixed defects, suggesting different causes for LV dysfunction. LV global function improved after surgery in 14 (54%) of the 26 patients; the improvement was more likely to occur in patients with normal scans and or reversible defects than in those with fixed defects ($p < 0.01$).

The occurrence of perioperative infarction, graft occlusion, or intraoperative ischemia may have contrib-

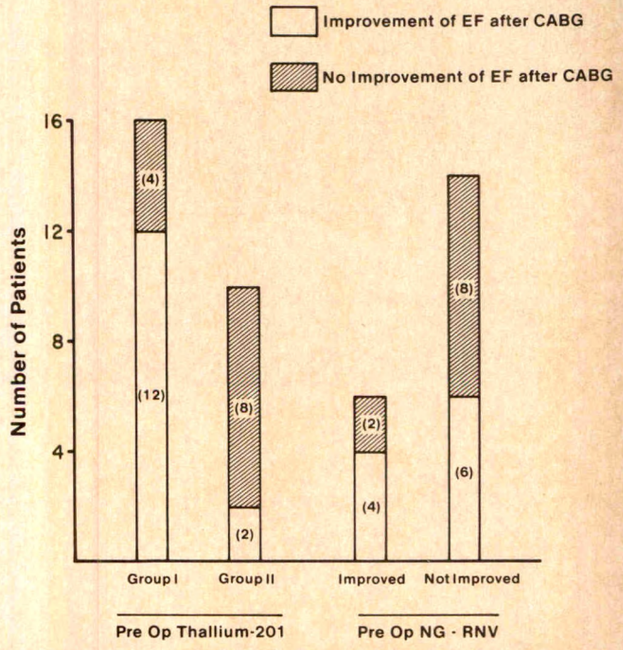

FIGURE 5. Changes in left ventricular ejection fraction (EF) after coronary artery bypass grafting (CABG) in relation to the results of preoperative (Preop) thallium-201 images and nitroglycerin (NG)-intervention radionuclide ventriculograms (RNV). Group I patients had normal scans or transient defects; Group II patients had fixed defects.

uted to the absence of improvement in EF in 2 patients (1 with reversible defect and 1 with normal scans). Similarly, it is not clear why the 2 patients with fixed defects showed improvement in LV function postoperatively. The changes in preload and afterload postoperatively in the second patient who had no change in thallium score may have contributed to the improvement. It appears, therefore, that rest and redistribution thallium imaging predicted the correct change in postoperative LV function in 83% of the patients, whereas the predictive accuracy of nitroglycerin-intervention radionuclide ventriculography was 60%. Finally, abnormal Q waves did not preclude improvement in LV function.

Clinical implications: Patients with abnormal LV function constitute a heterogeneous population that can be separated into such groups on the basis of the resting perfusion pattern. This study may provide guidelines for recommending bypass surgery in patients with coronary artery disease and minimal or no symptoms if improvement in LV function is the main indication for surgery. It should be emphasized that our results are related to resting LV function. Improvement in exercise LV function has been reported in most patients after coronary artery bypass surgery.[30]

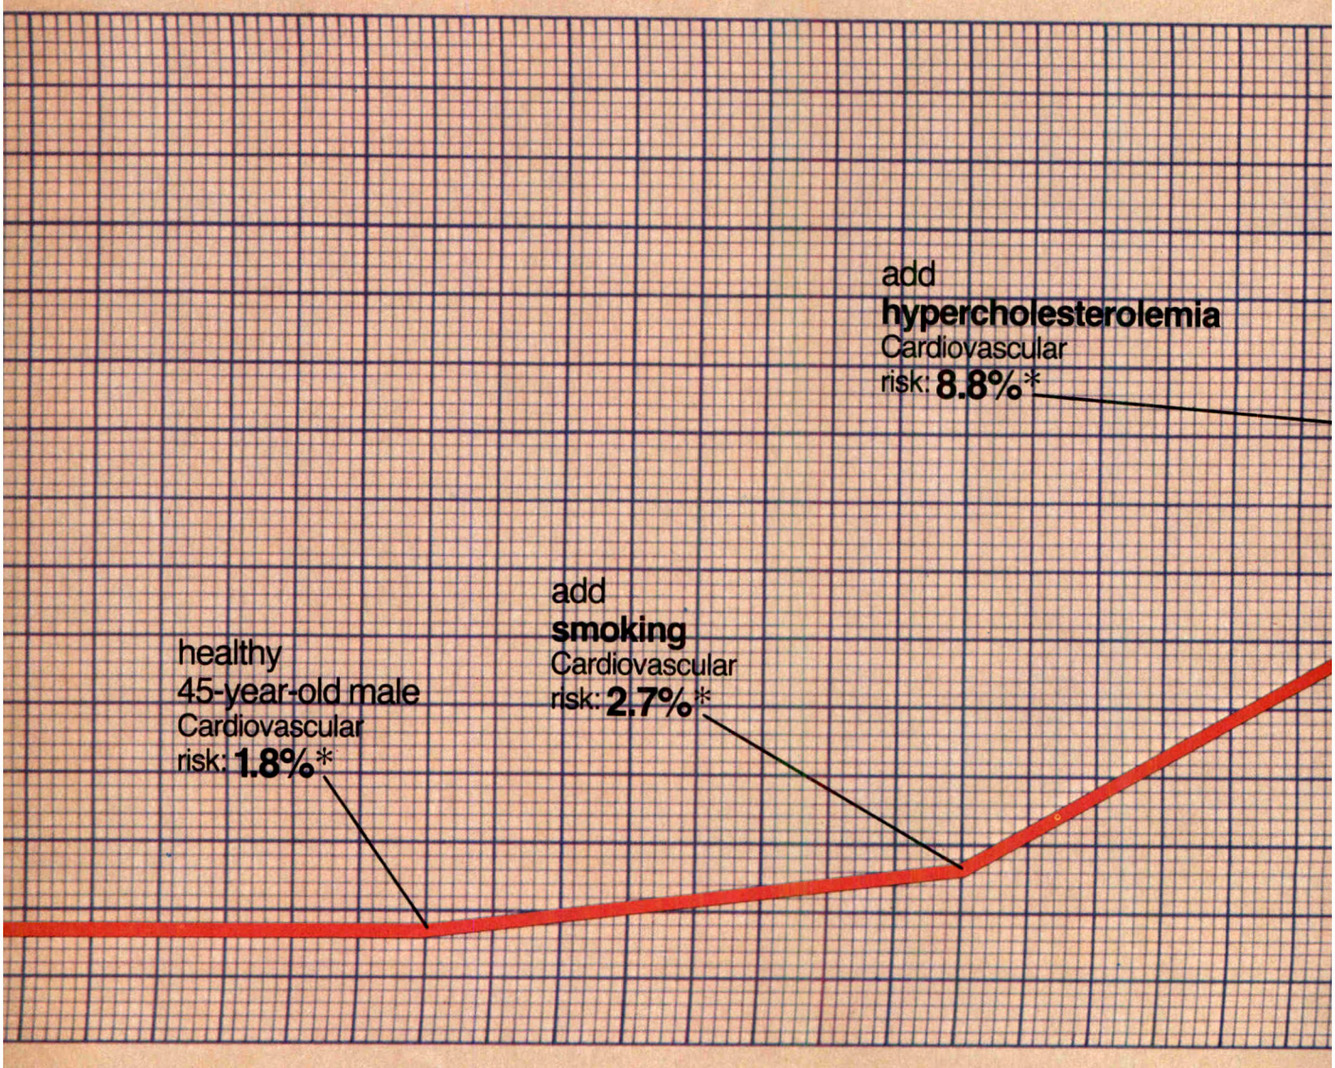
*Dioctyl Sodium Sulfosuccinate (Docusate Sodium)

In hypertensive patients

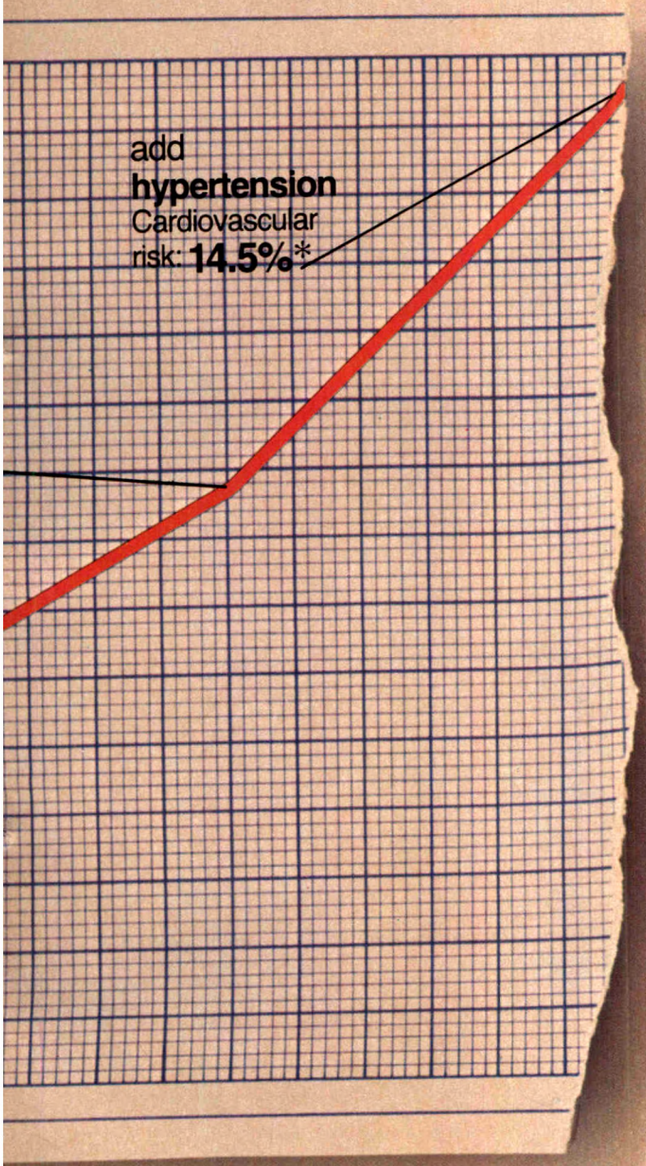


Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

Consider the Risks



▪ When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

▪ Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

▪ Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

Please see Minipress brief summary on following page.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

Minipress® (prazosin HCl) Capsules 1mg, 2mg, 5mg

B.I.D. Dosage Convenience

BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*
INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings.)

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

Rheumatology

A Primary Care Approach

Written by:

Bruce M. Rothschild, MD

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V. A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8 $39.50
430 pp., illus., November 1982,

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

Table of contents

Section 1 - Investigative Techniques, Chapter 1 - The Rheumatologic History and Physical Examination, Chapter 2 - Arthrocentesis and Joint Fluid Evaluation, Chapter 3 - Laboratory Studies, Chapter 4 - Radiology of Joint Disease, **Section 2 - Patterns of Disease,** Chapter 5 - Infectious Agent Arthritis, Chapter 6 - Arthritis of Mechanical Derivation, Chapter 7 - Crystalline Arthritis, Chapter 8 - Rheumatoid Arthritis, Chapter 9 - Juvenile Rheumatoid Arthritis, Chapter 10 - Ankylosing Spondylitis, Chapter 11 - Reiter's Syndrome and Psoriatic Arthritis, Chapter 12 - Arthritis Associated with Gastrointestinal Disease, Chapter 13 - Endocrine, Metabolic, and Deposition Disease, Chapter 14 - Arthritis Associated with Hematologic Disease, Chapter 15 - Miscellaneous Causes of Arthritis, Chapter 16 - Nonarticular Rheumatism, Chapter 17 - Systemic Lupus Erythematosus, Polymyositis, and Sjogren's Syndrome, Chapter 18 - Scleroderma, Chapter 19 - Vasculitis/Vasculopathy, **Section 3 - Management,** Chapter 20 - Approach to Diagnosis, Chapter 21 - Compliance and Quackery, Chapter 22 - Salicylate Pharmacodynamics, Chapter 23 - Medication Therapy, Chapter 24 - Rehabilitation Therapy, Chapter 25 - Surgical Intervention

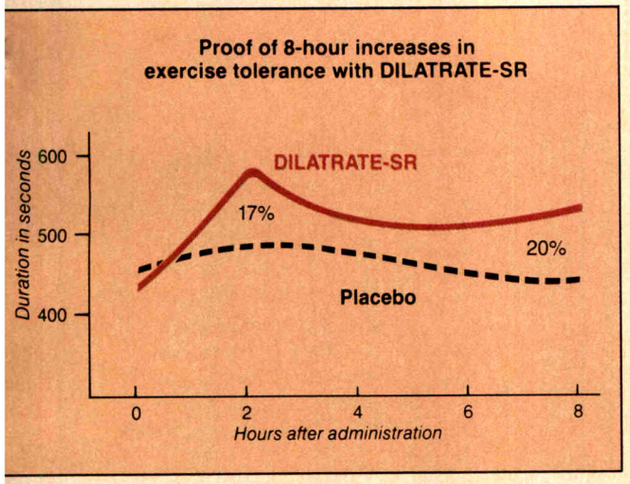
ONLY
DILATRATE®-SR
(isosorbide dinitrate)
HAS CLINICAL

treadmill tests, DILATRATE-SR produced a 17% crease in mean total exercise duration within 2 hours; ter 8 hours the increase was 20%.



*Exercise duration and work capacity increased for a full 8 hours in angina patients**

In a double-blind, placebo-controlled study involving patients with chronic stable angina, significant improvement in exercise capacity was sustained for eight hours following administration of one 40 mg DILATRATE-SR capsule.[1]

This is the first study to demonstrate that a sustained-release nitrate formula can provide clinical effectiveness for a full eight hours. And, the advantage over placebo did not appear to be decreasing at the end of eight hours.

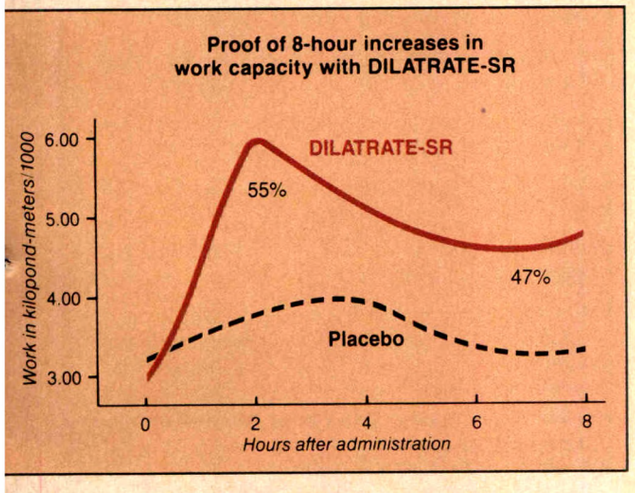
Increases in exercise tolerance translate into true patient benefits

Exercise tolerance tests provide objective measurements of improvement in work capacity that can be correlated with the anginal patient's daily activities. These results demonstrate that DILATRATE-SR can provide a positive impact on your patient's lifestyle.

Clinical support of plasma level studies

This clinical study supports previous blood assays which demonstrated that DILATRATE-SR provides significant plasma levels of ISDN for up to 12 hours.[2]

PROOF: 8-hour antianginal activity*



20% increase in duration of treadmill exercise means nother minute or two at higher speed on a steeper ncline. When mean work performance was calculated,)ILATRATE-SR provided a 47% increase at 8 hours.

A unique method of delivering isosorbide dinitrate

DILATRATE-SR employs a unique delivery system — an advanced microdialyzing membrane that releases ISDN at a steady rate independent of gastric pH and enzymes. The water-activated membrane continually adjusts permeability to maintain constant nitrate release.

DILATRATE-SR simplifies antianginal therapy

The proven sustained activity of DILATRATE-SR offers anginal patients convenient b.i.d. dosage and can reduce the need for sublingual nitroglycerin.

*Please see brief summary of full prescribing information on following page. For full prescribing information, consult package insert.

Dilatrate®-SR
(isosorbide dinitrate) 40 mg

Reed & Carnrick / Piscataway, New Jersey 08854

Dilatrate®-SR
(isosorbide dinitrate) 40 mg

BRIEF SUMMARY

Indications: Based on a review of this drug by the National Academy of Sciences – National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: When taken by the oral route, is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATION: Idiosyncrasy to this drug.

WARNINGS: Data supporting the use of nitrates and nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

PRECAUTIONS: Tolerance to this drug, and cross-tolerance to other nitrates or nitrites may occur.

In patients with functional or organic gastrointestinal hypermotility or malabsorption syndrome it is suggested that either the 5 mg. or 10 mg. oral tablets or 2.5 mg. or 5 mg. sublingual tablets be the preferred therapy.

ADVERSE REACTIONS: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

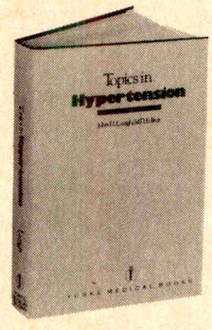
Laragh's eagerly awaited new book on the silent killer

TOPICS IN HYPERTENSION



Edited by
John H. Laragh, MD
Master Professor of Medicine
Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center

644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $55.00. Available on 30-day approval.

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

When patients need more potassium than tablets can easily offer...

©1982 Sandoz, Inc.

Consider the simplicity of KLORVESS® EFFERVESCENT GRANULES

Each packet (2.8 g) provides 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, and L-lysine monohydrochloride 0.913 g.

The patient on higher doses of antihypertensive medication, diuretics and/or digitalis, may need additional potassium supplementation...40 mEq/day or more. KLORVESS Effervescent Granules offer the following advantages:

- ***Each packet delivers 20 mEq of potassium***...compared with slow-release tablets that contain 10 mEq or less.
- ***Sparkling citrus flavor offers a high degree of patient compliance.*** Patients may even use KLORVESS as a "chaser" for other medications. Granules mix easily with cold water...no need for expensive juices to make palatable.
- ***Convenient effervescent granules dissolve almost immediately***...no waiting.
- ***Sugar-free, sodium-free, carbohydrate-free, dye-free formulation***...ideal for hypertensive, diabetic, or overweight patients.

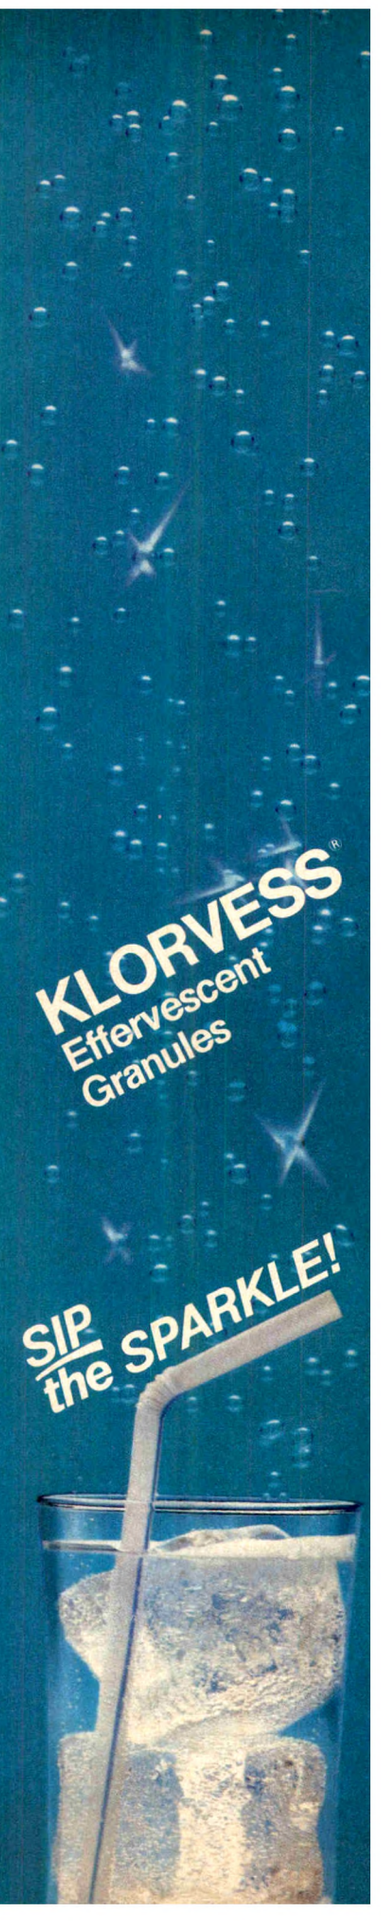
KLR-582-1



Give your patients the KLORVESS® sparkle

Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

Brief summary of prescribing information

DESCRIPTION: *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

INDICATIONS: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

CONTRAINDICATIONS: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

PRECAUTIONS: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

ADVERSE REACTIONS: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

DOSAGE AND ADMINISTRATION: *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.

OVERDOSAGE: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

HOW SUPPLIED: *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

OUR HANDS-ON

Microprobe.™

Go ahead, put your hand right over this photograph. It's actual size and it will give you a good idea of just how small our Microprobe™ really is. It's the smallest and lightest mechanical sector probe in Echocardiography. And you know the inherent imaging benefits of that. Like a phased array probe, Microprobe's™ small size provides maneuverability when performing difficult cardiology studies, not to mention operator and patient comfort. Our wide variety of probe frequencies, and our simple push-pull locking connector between the probe, coupled to a lightweight, flexible cable lets you change probes and applications in seconds. And we make them ourselves. All parts of the Microprobes™ are manufactured by EkoLine, which means we're sure of the quality and can maintain our advanced probe technology. Like the best conventional mechanical sector probes, Microprobe™ provides superior 2-D image quality. Plus it also gives you the best M-Mode in the industry. But don't take our word for it—try it on *your* difficult patients. Call Debbie Gentry toll free outside California at (800) 538-1556, inside California at (408) 732-6010 for a real hands-on demonstration.

(Actual Size)

E K O L I N E I N

In diagnostic ultrasound, Microprobe™ is a trademark belonging only to EkoLine.

DEMONSTRATION

EKO 5010.™
Our EKO 5010™ Ultrasound System proves the old adage that good things come in small packages. It combines ease of use, cost-effectiveness and portability with the best M-Mode in cardiology and superior 2-D cardiac imaging. And with the 5010, there is no compromise in image quality or electronics. That's because you get the same basic imaging capabilities found in our other systems. Like TGC control with 9 slide pots to optimize resolution and image quality throughout the entire field of view. Plus, when you add our Video Page Printer option, paper savings over the life of the instrument will pay for the system. And the Video Page Printer is one-third the cost of a strip chart recorder. And, of course, at the other end of all this is our exclusive Microprobe.™

EKO 5500D.™
Our EKO 5500D™ offers everything our 5010 does. And much more. It provides totally integrated pulsed and continuous wave doppler, for a complete diagnostic study. Plus, it's easy to operate. With the programmable footswitch, you can select the imaging modes you need—M-Mode, 2-D, doppler and strobe, allowing you to concentrate on the patient, not the system. But if your immediate needs don't call for doppler, there's the EKO 5000.™ It has all the features of the 5500 system, including automatic TGC, alphanumeric keyboard and strip chart recorder. And, you guessed it, all of our exclusive Microprobes™ simply plug right in.

EKO 5010™

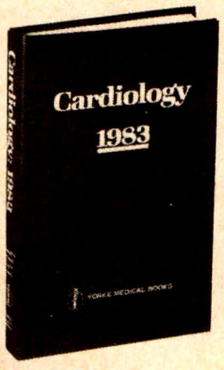
Practical References For the Busy Practitioner



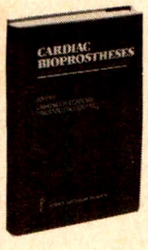
Cardiology 1983

Written by
William C. Roberts, MD
Dean T. Mason, MD
Thomas P. Graham, MD
Robert B. Karp, MD
Albert D. Pacifico, MD
Charles E. Rackley, MD
James T. Willerson, MD

Now in its third issue, CARDIOLOGY is quickly becoming the annual of first choice for physicians and scientists in need of a well organized, easy-to-use review of the year's newest and most important developments in cardiovascular medicine and surgery.

It continues to be a multidisciplinary approach to clinical and applied research as useful to the expert as it is to the novice.

ISBN 0-914316-36-2, approx. 500pp., illus., June '83, approx. $45.00



Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by,
Lawrence H. Cohn, MD,
Vincenzo Gallucci, MD

The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

Contributors from virtually every major cardiovascular center in the world that has had any meaningful experience with cardiac bioprosthetic valves participated in this symposium where 45 papers were presented in 8 categories.

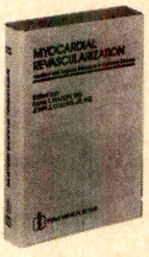
ISBN 0-914316-34-6, 596pp., illus., 1982, $65.00

Atlas Of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Foreword by David H. Spodick, MD

Dr. Alfredo Palacio has drawn on his rich experience to produce an atlas which presents in the simplest, most direct way possible the broadest range of normal and abnormal 2-dimensional echograms. Its excellent illustrations are complemented by beautiful drawings and supplemented by diagrams and explanatory texts which transcend the usual collection of illustrative material to explain methodology and provide the reader with a true "how-to-do-it" text. The descriptions and detailed illustrations in its technical sections should ensure the superior level of performance of echocardiographic techniques that is a *sine qua non* for good results.

ISBN 0-914316-35-4, 200pp., illus., large format 8¾×12, March '83, $65.00



Myocardial Revascularization

Medical and Surgical Advances in Coronary Disease

edited by
Dean T. Mason, MD,
John J. Collins, MD

The most up-to-date reference on the state-of-the-art of medical and surgical revascularization in clinical coronary disease available today. Presents many new therapeutic modalities not previously published anywhere.

"An excellent book on the major breakthroughs in an important area of medicine." MD magazine

ISBN 0-914316-31-1, 544pp., 1981, $60.00

Coming soon . . .

Postoperative Congenital Heart Disease

Rehabilitation In Ischemic Heart Disease

edited by William P. Blocker, MD, David Cardus, MD

Heavily illustrated, this volume presents 60 self-contained chapters dealing with *all* aspects of rehabilitation of the patient with ischemic heart disease. The 52 noted contributors discuss topics such as: designing a cardiac rehabilitation center; methods of rehabilitation for the stroke patient, amputee, spinal cord injury patient who has had a heart attack; equipment needs for a cardiac rehabilitation center; legal responsibilities of the physicians and therapists, and much, much more.

Your Right to Know... The Facts in Black and White

FACT: Calan® (verapamil HCl) is the calcium antagonist consistently demonstrating antianginal benefits equal to, or greater than, propranolol, at clinically used doses in angina of effort.[1,2,3,4,5,6]

- Calan is also effective in variant angina[7] (where spasm may be exacerbated by propranolol[8]) as well as in unstable angina.[9]

FACT: In direct-comparative studies, the antianginal benefits of Calan were reported to be unsurpassed by nifedipine.[10,11,12]

- In stable effort angina: "The trial demonstrated a clear difference in the antianginal efficacy of [verapamil (Calan) and nifedipine]. ...Verapamil [Calan] was more effective..."[10] In another study, the efficacy differences were not statistically significant.[11] The doses used in both studies were Calan 120 mg tid and nifedipine 20 mg tid.

  In variant angina, in the one published comparative study, Calan and nifedipine showed equal efficacy. However, this study was neither blinded nor randomized.[12]

- Studies were directly comparative, and responses to each drug were measured objectively.[10,11,12]

FACT: Calan is indicated as single-agent initial therapy for all types of angina, while nifedipine is not.[13,14]

- Nifedipine is indicated in stable effort angina only in patients refractory to or intolerant of nitrates and/or beta-blockers.[14]
- Nifedipine is indicated for unstable angina only when ECG findings indicate vasospasm or the disease is refractory to nitrates and/or beta-blockers.[14]

FACT: The potential serious cardiovascular side effects of Calan are similar to those of beta-blockers.

- Calan and propranolol have basically the same cardiovascular cautions and contraindications such as in patients with ventricular dysfunction, second- or third-degree AV block, or cardiogenic shock.[13,15] Calan is also contraindicated in the presence of sick sinus syndrome or hypotension.
- Calan rarely causes extreme fatigue or mental depression.
- Impotence, memory loss, or nightmares have not been associated with Calan use. Calan may cause constipation.
- Calan can be used without special caution in patients with angina who also have asthma, chronic obstructive pulmonary disease, diabetes mellitus, or peripheral vascular disease such as Raynaud's phenomenon.

FACT: The incidence of adverse effects of Calan and nifedipine merits comparison (see chart below).

Adverse Reactions Reported	nifedipine — Uncontrolled U.S. experience in 2,100 patients. The incidence of adverse reactions in controlled studies was generally the same or higher.[14]	(Calan) verapamil — Clinical studies in 1,166 patients — NOTE that similar results were seen in both controlled clinical trials and uncontrolled clinical experience.[13]
Dizziness, light-headedness	About 10%	3.6%
Constipation	2% or less	6.3%
Flushing	About 10%	*
Headache	About 10%	1.8%
Weakness	About 10%	*
Fatigue	*	1.1%
Nausea	About 10%	1.6%
CHF or pulmonary edema	**	0.9%
Peripheral edema	About 10%	1.7%
AV block: third-degree	*	0.8%
Transient hypotension	About 5%	2.9%
Palpitation	About 2%	*
Bradycardia: HR<50/min	*	1.1%
Syncope	About 0.5%	<0.5%

*Not reported in the prescribing information.[13,14]

**About 2%, "not readily distinguishable from the natural history of the disease." "It remains possible, however, that some or many of these events were drug related."[14]

Calan® (verapamil HCl) **TABLETS** 80 mg and 120 mg

Effective Angina Therapy

Please see reverse side for a brief summary of the complete prescribing information.

© 1982, Searle Pharmaceuticals Inc.

The Facts of Effective Angina Therapy

FACT: Calan® (verapamil HCl) has pharmacologic effects complementary to those of nitrates.[13]

- Like propranolol, Calan decreases myocardial contractility. Calan's effect on the SA node tends to minimize heart rate response to arterial vasodilation, leaving the rate unchanged or slightly reduced.[13]
- Nifedipine tends to cause slightly increased heart rate due to a sympathetic response to arterial dilation.[14]

FACT: Calan provides truly additive effects with propranolol when such combination therapy is necessary in the treatment of chronic stable angina.[3,4]

- In two studies involving a total of 33 patients, the additive effects of Calan with propranolol on exercise tolerance could be seen.

	Study A[3]	Study B[4]
Propranolol alone	+2 min *	+1.3 min
Calan alone	+3.2 min	+3.4 min
Calan with propranolol	+5.3 min	+4.7 min

*Difference from placebo to maximally tolerated exercise

- Combined therapy should be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function. Because of the still limited experience with combination therapy, Calan should be used alone, if possible.

FACT: Safety considerations are important with Calan, beta-blockers, and nifedipine.

- In patients with normal conduction, Calan's electrophysiologic effects are rarely clinically important.[13] However, Calan's contraindications include patients with sick sinus syndrome or second- or third-degree AV block.
- The concomitant use of digitalis with Calan or nifedipine requires caution because digoxin serum levels may increase.[16,17]
- Both Calan and nifedipine, as well as propranolol and nitrates, require monitoring during upward dose titration.[13,14,15]

For Your Patients With Angina...

Calan® TABLETS 80 mg and 120 mg
(verapamil HCl)

- Calan is the calcium antagonist with consistently demonstrated antianginal benefits equal to or greater than propranolol.
- Calan is effective in variant angina where spasm may be exacerbated by propranolol.[8]
- Calan, unlike nifedipine, has a first-line indication for stable effort angina.

FACT: All the above statements are supported by published materials.

Calan® (verapamil HCl) TABLETS 80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings),* hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Occasional elevations of liver enzymes have been reported; patients receiving verapamil should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil. **Precautions:** Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefuly monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR< 50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** Calan (verapamil HCl) is supplied in 80-mg and 120-mg sugar-coated tablets.

Long-Term Converting-Enzyme Inhibition As a Guide to Surgical Curability of Hypertension Associated With Renovascular Disease

JAN STAESSEN, MD, CHRISTOPHER BULPITT, MD, ROBERT FAGARD, MD, PAUL LIJNEN, PhD, and ANTOON AMERY, MD

Converting-enzyme inhibition as a guide to the hypotensive response to be expected from surgery was evaluated in 27 hypertensive patients with renovascular disease. Blood pressure averaged 163 ± 5/102 ± 2 mm Hg (mean ± standard error of the mean) during converting-enzyme inhibition with captopril, 518 ± 29 mg daily for 2.8 ± 0.3 months, and stabilized at a similar level of 165 ± 4/104 ± 3 mm Hg during 5.0 ± 0.6 months of postoperative follow-up, when no medication was administered.

Postoperative pressure, both systolic ($r = +0.53$; $p = 0.004$) and diastolic ($r = +0.55$; $p = 0.003$), was correlated with blood pressure during converting-enzyme inhibition. In addition, multiple regression analysis identified systolic pressure during converting-enzyme inhibition as the only significant ($p < 0.01$) predictor of postoperative systolic pressure. Diastolic pressure during converting-enzyme inhibition ($p < 0.05$) in conjunction with circulating renin ($p < 0.05$) and renin suppression from the contralateral kidney ($p < 0.01$) explained up to 53% of the postoperative diastolic pressure. Therefore, blood pressure during long-term converting-enzyme inhibition may be useful as a predictor of the postoperative blood pressure in hypertensive patients with renovascular disease.

Pharmacologic inhibition of the renin-angiotensin system has been proposed as a means of detecting angiotensin II dependence and hence surgical curability of hypertension in human renovascular disease. Bühler et al[1] reported that the hypotensive response to propranolol and to successful surgery was generally of the same magnitude in patients with renovascular or unilateral renal parenchymal disease. More recently, saralasin testing has been employed in the recognition of "angiotensinogenic" renovascular hypertension, but both false-positive and false-negative results have been reported.[2–4] Furthermore, short-term administration of inhibitors of the renin-angiotensin system is likely to be an unreliable guide to surgical prognosis.[5] Therefore, the present study investigates whether long-term converting-enzyme inhibition with captopril could be useful in predicting the postoperative blood pressure in hypertensive patients with renovascular disease.

Methods

Patients: After informed consent was obtained, 27 hypertensive patients, 21 men and 6 women, were given captopril and later operated on. These patients, aged 47 ± 3 years (mean ± standard error of the mean) and weighing 73 ± 3 kg, were selected after renal angiography demonstrated an arterial diameter reduction of ≥50%. However, blood pressure response to converting-enzyme inhibition was never employed as an index as to whether or not surgical treatment should be proposed. Renal artery stenoses were caused by atheromatosis (n = 20), fibromuscular hyperplasia (n = 4), or trauma (n = 1), whereas in the remaining 2 patients contrast studies revealed at 1 side a hypoplastic renal artery. Using the World Health Organization criteria (1978), hypertensive cardiovascular disease had progressed to stage 2 in 10 patients and to stage 3 in 13 patients. The serum creatinine level averaged 1.4 mg/dl, ranging from 0.6 to 3.1 mg/dl.

Diagnostic procedures: Before the study renal angiography was performed and obstructive lesions were graded by an independent observer. On a separate day, after overnight

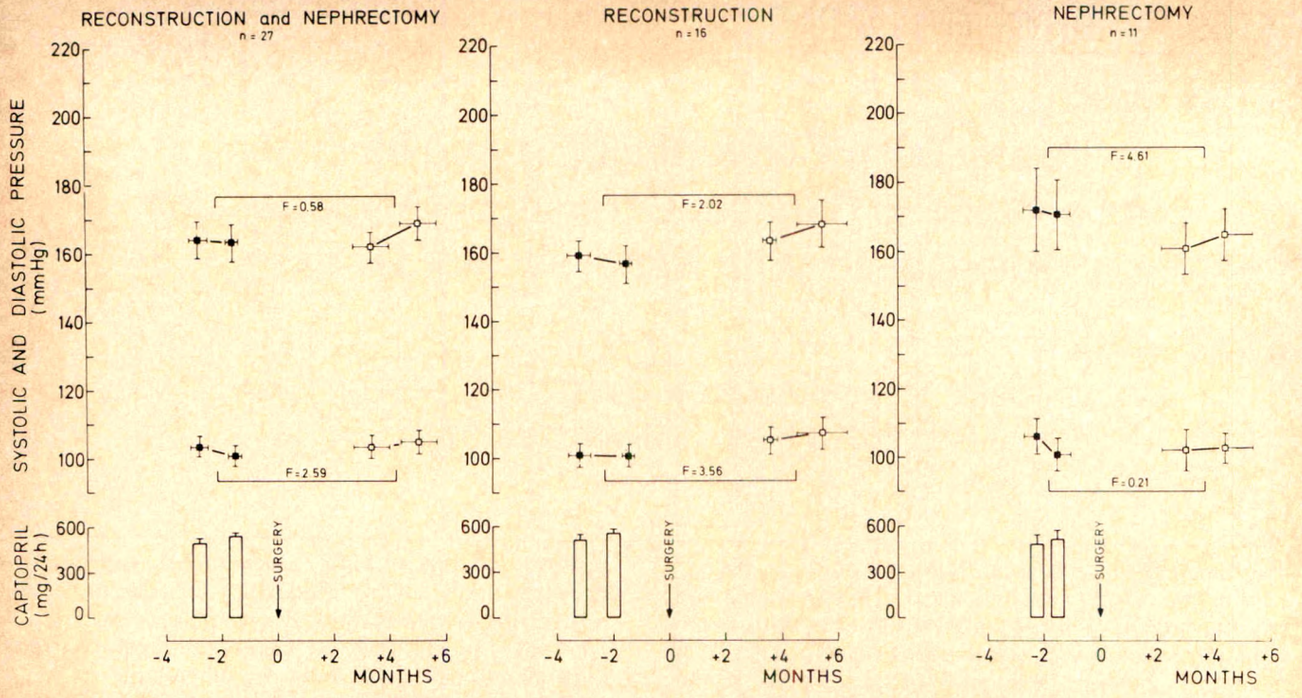

FIGURE 1. Systolic and diastolic blood pressure (mean ± standard error) during converting-enzyme inhibition (**closed symbols**) and postoperative follow-up study (**open symbols**) are given for the total study population (n = 27) and for patients subjected to renal revascularization (n = 16) and nephrectomy (n = 11), separately. The daily dose of captopril is indicated in the lower part of the illustration.

recumbency, blood samples were selectively obtained from the right and left renal vein together with an arterial blood sample. At least 2 consecutive days before the latter procedure, renin secretion had been stimulated by dietary sodium restriction to 50 mEq/24 h and by the administration of a diuretic agent, in most instances chlorthalidone 50 mg/day. Other hypotensive drugs were withheld at least 1 week before renal vein catheterization. When bilateral arterial lesions were present (7 patients), the ipsilateral side was identified as the side with the higher grade stenosis which in all these patients also showed the higher renal vein renin activity.

Study protocol: At the start of the study 18 patients were not receiving antihypertensive medication, whereas in 9 patients medical therapy had been continued for ethical reasons. After entering the study patients were started on (n = 18) or switched to (n = 9) monotherapy with captopril in 3 divided daily doses. The dose of the converting-enzyme inhibitor was doubled every 2 weeks until normotension was achieved or until side effects occurred. A ceiling daily dose of 600 mg was reached in 21 patients: 2 patients were finally prescribed a maximal daily dose of 450 mg and 3 other patients 300 mg, whereas 1 patient became normotensive while taking only 25 mg daily. Captopril treatment was continued on average for 2.8 ± 0.3 months (range 3 to 29 weeks). Thereafter patients came to surgery. Of the 20 patients with unilateral lesions, 12 underwent revascularization and 8 nephrectomy at the diseased site. Of the 7 patients with bilateral renal artery lesions, 2 were subjected to a bilateral bypass operation and 1 to ipsilateral nephrectomy and contralateral revascularization. For further analysis, the latter patient will be classified in the nephrectomy group of patients, because this procedure relieved the functionally significant lesion. Contralateral renal artery lesions were graded <50% in 4 patients who had an ipsilateral to contralateral renal vein renin ratio >2.1. In these 4 patients only the ipsilateral lesion was relieved by either nephrectomy (n = 2) or a bypass operation (n = 2). During the postoperative follow-up averaging 5.0 ± 0.7 months (range 8 to 74 weeks), the patients did not receive hypotensive drug treatment. After renovascular surgery, the patency of the renal artery or its bypass graft was always verified arteriographically.

Patients were examined at regular intervals and always in the early afternoon: results of 1 outpatient visit at the start of the study and of 2 visits during preoperative captopril treatment and postoperative follow-up will be reported. On each visit, blood pressure was measured 5 times consecutively in the supine position. The last 2 pressure readings of each visit were averaged for statistical analysis. The untreated blood pressure available in 18 patients was the pressure recorded in the outpatient clinic after many visits, when the patient had become accustomed to both procedure and visit. Blood was withdrawn from an antecubital vein after the patient had been seated for 15 minutes (during converting-enzyme inhibition approximately 8 hours after the morning dose of captopril). Blood tests included erythrocyte and leukocyte counts and creatinine, blood urea nitrogen, and renin activity determinations,[6] and during captopril treatment and postoperative follow-up also angiotensin I[7] and angiotensin II determinations.[8] Twenty-four–hour urine samples were analyzed for sodium, creatinine, aldosterone,[9] and prostaglandin E_2[10] and $F_{2\alpha}$.[10]

Statistical analysis: Statistical methods included Student's t test for paired observations and 3-way analysis of variance on treatments (captopril versus surgery), order of investigations, and subjects. Proportions were compared by McNemar's test. Regression analysis was performed after linearizing the distribution of plasma renin by a logarithmic transformation. Postoperative blood pressure was correlated with various predictors using Pearson's correlation coefficient. To evaluate the independent contributions of these predictors

to the postoperative pressure, multiple regression equations were calculated by a step-down procedure, terminating when all retained regression coefficients were significant at the 5% level.[11]

Results

Effects of converting-enzyme inhibition and surgery: In the 18 initially untreated patients, arterial pressure decreased ($p < 0.001$) from 194 ± 8/122 ± 4 mm Hg to 154 ± 4/97 ± 3 mm Hg during captopril treatment and stabilized at 161 ± 6/105 ± 4 mm Hg during postoperative follow-up. In these patients captopril produced an increase ($p < 0.001$) in plasma renin activity from 6.6 ± 2.5 to 17.1 ± 2.8 ng/ml/h. Nine patients were still on hypotensive drug treatment at the start of the study, when their blood pressure averaged 189 ± 12/113 ± 6 mm Hg. During captopril intake their pressure was decreased to 182 ± 11/110 ± 4 mm Hg and postoperatively to 174 ± 6/103 ± 4 mm Hg, but these effects were statistically not significant.

Comparison between converting-enzyme inhibition and surgery: Analysis of variance showed that independent of the nature of treatment (converting-enzyme inhibition or surgery), none of the variables was influenced by the order of the observations; therefore, average values will be reported for both outpatients during each treatment period.

As shown in Figure 1, blood pressure levels were similar during captopril treatment and postoperative follow-up when all patients (n = 27) were considered together. This also was true when patients subjected to vascular surgery (n = 16) or nephrectomy (n = 11) were analyzed separately.

Results of relevant blood and urine analyses performed during captopril treatment and postoperatively are presented in Tables I and II, separately for patients subjected to reconstructive vascular surgery (n = 16) and nephrectomy (n = 11). In both groups serum creatinine and blood urea nitrogen decreased after surgery compared with results after captopril treatment, whereas the changes in creatinine clearance, although in the same direction, did not reach a level of statistical significance. This could be related to the higher variability of the latter measurement. Plasma renin activity ($p < 0.001$) and angiotensin I ($p < 0.001$) decreased after either operative procedure. In contrast, angiotensin II and aldosterone were similar during converting-enzyme inhibition and after surgery. Compared with its value during converting-enzyme inhibition, the angiotensin I/angiotensin II ratio declined from 59 ± 12 to 5 ± 1 in patients subjected to renal revascularization (n = 15; $p < 0.001$) and from 112 ± 21 to 8 ± 2 in patients with nephrectomy (n = 9; $p < 0.001$), confirming that during captopril administration a smaller proportion of circulating angiotensin I was converted to angiotensin II. Prostaglandin E_2 and $F_{2\alpha}$ were not affected in 8 patients subjected to renal revascularization, whereas prostaglandin $F_{2\alpha}$ decreased ($p < 0.01$) in 6 patients with nephrectomy.

At the start of the study urinary output and urinary sodium excretion averaged 1.8 ± 0.1 liters/24 h and 118 ± 17 mEq/24 h, respectively, and thereafter did not change significantly, suggesting that patients remained on a constant sodium intake. Separate analysis of patients with bilateral renal artery stenosis is presented in Table III. Also in these patients, blood pressure and angiotensin II levels were similar during both treatment periods, whereas renal function improved after surgery.

TABLE III Results in 7 Patients With Bilateral Renal Artery Stenosis

	n	Captopril Treatment	Postoperative Follow-Up
Systolic pressure (mm Hg)	7	166 ± 10	161 ± 7

Significance of the difference between preoperative captopril treatment and postoperative follow-up: * $p < 0.001$, † $p < 0.01$, ‡ $p < 0.05$.
n = number of patients included in the analysis.

Prediction of postoperative blood pressure: Postoperative blood pressure, both systolic and diastolic, correlated positively ($p < 0.01$) with the pressure level during converting-enzyme inhibition (Fig. 2). Also, there was a significant and positive relation between postoperative diastolic pressure and the contralateral renal vein to arterial renin ratio ($r = +0.55$; $p < 0.01$). In the 18 patients in whom measurements of untreated blood pressure were available, it was possible to compare the predictive power of these readings with the prediction based on captopril pressures. For these subjects untreated pressures were correlated with postoperative pressures, yielding correlation coefficients of +0.45 for systolic and +0.44 for diastolic pressure ($p = 0.06$). The corresponding results for the captopril and postoperative pressures were +0.64 ($p = 0.004$) and +0.75 ($p < 0.001$) in these 18 patients. The captopril pressure predicted systolic and diastolic postoperative pressure within ±20 mm Hg in 67 and 78% of these 18 patients, respectively. This was significantly ($p = 0.05$) better than the 28% prediction with untreated systolic pressure, but not significantly better than the 50% prediction with untreated diastolic pressure. In this study it was not investigated whether the blood pressure prediction by another drug would give a worse or better result.

Stepwise multiple regression analysis identified systolic pressure during captopril administration as the only significant predictor of systolic pressure after surgery (postoperative systolic pressure = 0.45 systolic pressure during captopril + 91.9; $r = 0.53$; $p < 0.01$). However, the partial correlation between postoperative systolic pressure and arterial plasma renin activity (measured at the time of renal vein catheterization) just failed to reach statistical significance ($t = -2.01$; $p = 0.056$). For postoperative diastolic pressure the following equation was derived: postoperative diastolic pressure = 0.54 diastolic pressure during captopril − 10.5 $\log_{10}$ arterial plasma renin activity + 19.7 contralateral renal vein to arterial renin ratio + 40.5 ($r = 0.73$; $p < 0.001$). This equation indicates that the hypotensive potential of surgical treatment increased when captopril was more effective in reducing blood

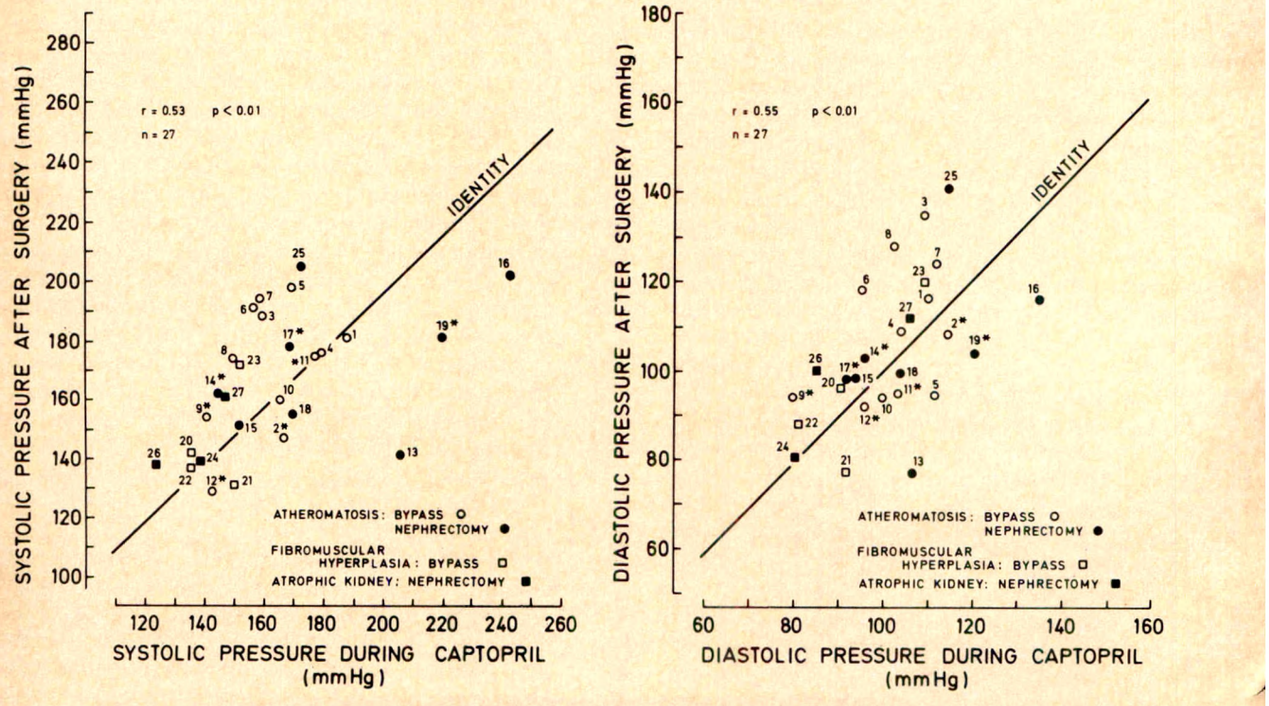

FIGURE 2. Systolic (**left**) and diastolic (**right**) pressure observed after surgery is plotted on the y axis against the pressure levels achieved by converting-enzyme inhibition (captopril) on the x axis. **Symbols** indicate for each patient, identified by the same number of both panels, the underlying condition and the surgical procedure used: **open circles** = atheromatosis and bypass; **closed circles** = atheromatosis and nephrectomy; **open squares** = fibromuscular hyperplasia and bypass; and **closed squares** = renal parenchymal atrophy and nephrectomy. **Asterisks** indicate patients with bilateral renal artery stenoses.

pressure ($p < 0.05$), when the peripheral (arterial) renin level was more elevated ($p < 0.05$), and when renin secretion from the contralateral kidney was more suppressed ($p < 0.01$). The regression equations, just indicated, were not materially altered by excluding from analysis patients with bilateral lesions. The following variables did not contribute to the prediction of postoperative blood pressure: (1) the ipsilateral renal vein to arterial renin ratio[12]; (2) the ipsilateral to contralateral renal vein renin ratio[13]; (3) venous renin during captopril treatment[14]; (4) patients' ages; (5) surgical procedure used (either vascular reconstruction or nephrectomy); (6) and uni- or bilateral localization of the vascular lesions.

Performance of a scoring system[12] in predicting curability: Fourteen patients with unilateral renovascular disease, not receiving treatment at the start of the study, showed a simple correlation coefficient of 0.81 between the diastolic pressure during captopril administration and that after surgery. These patients were also assessed using the scoring system proposed by Vaughn et al.[12] A successful outcome was defined[12,15] as one in which the patients either achieved normotension or had a decrease in diastolic pressure of >75% to a level <110 mm Hg. Eight patients with a point score[12] ≥5 should have been good candidates for operation, but subsequent surgery improved[12,15] diastolic pressure in only 4. In addition, 2 of 6 patients with a score <5 became normotensive.

Discussion

The purpose of the present study was to compare the effects of long-term converting-enzyme inhibition with the results of surgery in hypertensive patients with renovascular disease and to evaluate the value of long-term captopril administration in predicting surgical outcome.

Comparison of results with converting-enzyme inhibition and surgery: Average blood pressure levels were similar during converting-enzyme inhibition and after surgery. This was true not only when all patients were considered together, but also when patients subjected to renovascular surgery or to nephrectomy or when patients with bilateral lesions were analyzed separately. Atkinson et al,[5,16] using captopril at a daily dose of only 450 mg, also reported successful inhibition of the plasma renin-angiotensin-aldosterone system and similar pressure levels during long-term converting-enzyme inhibition and after surgery in their patients with unilateral renal artery stenosis.

Preservation of renal function is an important consideration in the management of patients with renovascular disease.[17] Atkinson et al[16] recently reported that serum creatinine was not affected when patients, preoperatively treated with captopril, were followed up after nephrectomy ($n = 8$) or renovascular surgery ($n = 2$). In contrast, the present study demonstrated that the average serum creatinine and blood urea nitrogen levels were decreased after surgery as compared with captopril treatment. This observation may have clinical relevance. Renovascular hypertension is one of the major indications for converting-enzyme inhibition, and long-term captopril treatment may be considered as an alternative to surgical management. However, the present findings could suggest that patients with incipient renal insufficiency might benefit from an operation. However, the changes in creatinine clearance were not significant, and further studies using a smaller dose of captopril will be needed to clarify this issue.

Renin activity and endogenous angiotensin I levels remained high during converting-enzyme inhibition, but decreased after surgery when the patients were not on antihypertensive medication. Angiotensin II levels were similar pre- and postoperatively, but the angiotensin I to angiotensin II ratio declined strikingly, confirming that the converting enzyme was effectively inhibited during the preoperative period. Eighty percent of these measurements were made while the patients were taking a ceiling daily dose of 600 mg of captopril. However, some investigators[18] have reported that a single dose as small as 20 mg is able to block the pressor effect of exogenous angiotensin I for as long as 2.5 hours. Furthermore, in a chronic outpatient study we demonstrated that both the hypotensive effect and the inhibition of the plasma angiotensin II-aldosterone system plateau at a daily dose of 150 mg.[19] Therefore, the dose that we prescribed in the present study was greater than that required to inhibit the renin-angiotensin system. During captopril treatment agranulocytosis occurred in 1 patient,[20] but in no patient was proteinuria or a further impairment of renal function observed.

Urinary prostaglandins were measured in this study in view of recent evidence implicating a positive feedback mechanism between the opposing renin-angiotensin and kallikrein-prostaglandin systems.[21] Endogenous prostaglandins may also be involved in the hypotensive action of captopril.[22] However, no changes in urinary prostaglandins were found in patients subjected to renovascular surgery, whereas the decrease in urinary prostaglandin excretion, observed in patients with nephrectomy could merely reflect the reduction in renal mass by which these prostaglandins are synthesized.

With regard to blood pressure control, our results of surgical treatment seem somewhat less favorable than those reported in the literature.[12,17,23] However, our study differs from the others[12,17,23] in the patients' age distribution and in the proportion of patients with fibromuscular dysplasia (for example, 15% versus 36% in the Cooperative Study). The observation that blood pressure was smaller in our patients probably cannot be attributed to surgical failure, because patients undergoing nephrectomy had an anatomically successful procedure by definition, whereas in all patients subjected to renovascular surgery the patency of the renal artery or its bypass were verified angiographically.

Predictive value of long-term converting-enzyme inhibition: The blood pressure levels during converting-enzyme inhibition and after surgery were correlated. The first-order correlation coefficients indicated that the pressure level achieved by converting-enzyme inhibition explained by itself approximately one third of

the variability of the postoperative blood pressure. Atkinson et al[5] found somewhat higher correlation coefficients (0.74 [$p < 0.02$] for systolic and 0.68 [$p < 0.05$] for diastolic pressure), but only after the blood pressure distributions were transformed logarithmically, whereas in the present study the relation was not improved by such a transformation.

The value of long-term captopril therapy as a guide to surgical treatment was further evaluated in relation to other known predictors by stepwise multiple regression. This analysis indicated that blood pressure during converting-enzyme inhibition was the only significant predictor of systolic pressure after surgery. The multiple regression equation derived for diastolic blood pressure indicated that the hypotensive effect of surgery increased when blood pressure was lower during long-term converting-enzyme inhibition, when renin release from the contralateral kidney was more suppressed, and when circulating renin was more elevated during moderate sodium depletion. These 3 variables, known at the time of the operation, predicted postoperative diastolic pressure with an accuracy of 10 mm Hg in all but 4 of the present patients. The diagnostic value of contralateral renin suppression has been demonstrated previously,[12,24] whereas that of peripheral renin remains much debated. Several investigators have observed normal levels of renin and angiotensin II even in patients with proven renovascular hypertension.[25,26]

Hyperreninemia during long-term converting-enzyme inhibition, in contrast to that after acute angiotensin II receptor blockade,[14] did not contribute to the prediction of postoperative blood pressure. The same was also true for renin stimulation at the ipsilateral site, even when the presence of bilateral lesions was taken into account or when patients with bilateral lesions were excluded from analysis. This observation contrasts with other studies in which excessive renin secretion by 1 kidney was defined retrospectively in terms of the ipsilateral to contralateral renal vein renin ratio.[13]

When a scoring system[12] based on the relative difference between renal vein and arterial renin was used to predict surgical curability in initially untreated patients with unilateral stenosis, 57% of these patients were correctly classified as potential responders to surgery,[12] whereas diastolic pressure during converting-enzyme inhibition correctly classified (with respect to postoperative diastolic pressure) 81% of the 27 patients to within ±20 mm Hg and 52% to within ±10 mm Hg. Although pressure during long-term converting-enzyme inhibition appeared to be a better predictor of the outcome pressure than a baseline but untreated pressure, it must be admitted that we have not proven captopril to be better than a nonspecific hypotensive drug, and this comparison remains to be made.

Acknowledgment: The present study is the result of many years of close cooperation with the Department of Radiology (Prof. Albert Baert, MD), Urology (Profs. Herman Verduyn, MD and Raoul Vereecken, MD), and Cardiovascular Surgery (Profs. Georges Stalpaert, MD and Raphael Suy, MD), University Hospital Sint Rafaël, Leuven, Belgium. Renaat Grauwels, BSc, performed the computer analyses. Expert clerical assistance was provided by Vivian Mariën and Yvette Toremans. We thank the Squibb Institute for Medical Research, Princeton, New Jersey, for the generous supply of captopril.

Nifedipine Tablets for Systemic Hypertension: A Study Using Continuous Ambulatory Intraarterial Recording

ROBERT S. HORNUNG, BSc, MRCP, BRIAN A. GOULD, MB, MRCP, RODERICK I. JONES, MB, MRCP, TANSUKH N. SONECHA, MB, MRCP, and EDWARD B. RAFTERY, BSc, MD, FRCP

The action of nifedipine tablets was examined in 17 patients with essential hypertension focusing particularly on the profile of blood pressure (BP) reduction over 24 hours resulting from both twice-daily and once-daily therapy (dose range 40 to 120 mg daily). This new formulation of nifedipine has a more prolonged and lower peak plasma level than an equivalent dose of nifedipine capsules. Our patients were fully ambulant and studied by continuous intraarterial recording techniques. BP responses during isometric and dynamic exercise testing were also observed. Within-patient comparisons of consecutive mean hourly systolic and diastolic BP showed a highly significant effect from twice-daily therapy ($p < 0.001$) for nearly the entire day. Also, significantly lower BP was maintained during isometric and dynamic exercise. Mean hourly heart rates were not significantly altered. The profile of action of the single morning dose was initially similar, but its efficacy diminished from 6 P.M. to 8 A.M. on the following day. Side effects were not unduly troublesome and did not cause any patient withdrawals. Four patients developed mild ankle edema. Two others had facial flushing.

Nifedipine given twice daily in tablet form, therefore, is an effective antihypertensive drug capable of lowering BP consistently over 24 hours in ambulant patients and during formal exercise testing. We suggest that this agent may be useful as initial therapy for systemic hypertension, although the tablets are not as yet widely available.

Nifedipine inhibits the inward flux of calcium ions across vascular smooth muscle and myocardial cell membranes. The vasodilatation that is produced may be observed in the coronary arteries but is predominant in the peripheral resistance vessels of the systemic circulation.[1] Hence this drug is not only useful in angina pectoris but also has potential as an antihypertensive agent. The effects of chronic treatment with nifedipine in hypertensive patients have previously been assessed using indirect methods of blood pressure (BP) measurement, mainly the standard mercury-in-glass sphygmomanometer.[2,3] The shortcomings of such methods have long been recognized, particularly the lack of information about BP during normal activities away from the hospital environment, throughout the day and night. Our aim was to study the profile of BP reduction over 24 hours resulting from nifedipine therapy in fully ambulant subjects by continuous intraarterial recording, using a new tablet formulation. This has slower release characteristics and produces lower peak plasma levels than the more familiar capsule formulation. We compared the action of once- and twice-daily therapy focusing particularly on any differences in the 24-hour control level of BP. We also examined the effects of twice-daily therapy on the response to a program of standardized physiologic tests to determine how the increase in BP induced by different forms of exercise was influenced by nifedipine.

Methods

This was an open study of patients selected from the Harrow Hypertension Clinic. Since it has been shown that there are no placebo effects on intraarterial blood pressure recorded by the methods used in this study,[4] a placebo controlled

crossover trial design was considered unnecessary. Patients were considered for inclusion in the study if they had recently diagnosed untreated hypertension or if their BP was inadequately controlled on existing medication. Criteria for acceptance were mean BP recorded from 3 separate clinic visits >160 mm Hg systolic or >95 mm Hg diastolic (Korotkoff phase V), or both, using a standard mercury-in-glass sphygmomanometer. Each patient had a full clinical examination and laboratory screening tests to exclude secondary hypertension. No patient had greater than grade 2 hypertensive retinopathy or a blood urea level >10 mmol/liter. Five patients had clinical or electrocardiographic evidence of left ventricular hypertrophy. Before entry into the trial (marked by the date of the first intraarterial monitoring), all antihypertensive medication was withdrawn, so that all patients had been untreated for at least 4 weeks.

The technique of ambulatory BP recording has previously been fully reported.[5] Briefly, the patients were required to attend the hospital for percutaneous insertion of an intraarterial cannula into the brachial artery of the nondominant arm with use of local anesthesia. Cannulation was performed in the same area at each subsequent recording. The BP signal and the electrocardiogram from bipolar chest leads were recorded using a specially designed transducer/perfusion unit and a Medilog Mark I cassette tape recorder (Oxford Instruments). The latter also incorporated a time channel with an event marker. The equipment was lightweight and portable so that patients were fully ambulant and could carry out their usual daily activities, and sleep at home.

At the beginning of each study, after insertion of the cannula, each patient underwent a standard protocol of physiologic tests. This consisted of an initial 20-minute period of rest in the supine position, followed by head-up tilt to 60° (after warning) maintained for 5 minutes. Isometric exercise was then performed using a hand grip dynamometer for 2 minutes at 50% of maximum voluntary contraction. Any tendency to produce a Valsalva reflex was avoided by requesting the patient to count aloud. After a 2-minute rest period, each patient then performed continuous dynamic exercise on a bicycle ergometer with work loads increasing from 250, 400, 700 to 1,000 kilopond-meters (kpm) at 3-minute intervals. Exercise was stopped when requested by the patient. After a 5-minute recovery period in the supine position and equipment calibration, patients then resumed their normal daily activities, returning to the hospital only for equipment checks and recalibration, to allow for any signal drift (usually not more than 5 mm Hg), at about 12-hour intervals. Recordings were continued for 24 to 36 hours; the cannula was then withdrawn, hemostatis achieved, and the equipment removed.

Each patient was then started on nifedipine tablets, 20 mg taken twice daily at 8 A.M. and 8 P.M., increasing to 40 mg twice daily after 4 weeks if necessary, and subsequently to a maximum of 60 mg twice daily depending on clinic BP recordings taken at 2-weekly intervals. When clinic BP appeared optimally controlled and stable (usually after 2 to 3 months' therapy), a second intraarterial recording was performed exactly as just described.

Patients were then changed to a once-daily regimen of the same total dosage of nifedipine tablets taken at 8 A.M. and restudied without the exercise protocol of after a minimum treatment period of 4 weeks.

Analysis of data: The tape recordings were initially replayed and written out using a linear direct-writing recorder (Watanabe). This allowed assessment of the analog signal quality, and editing of any artifact. Consecutive hourly mean values of BP and heart rate were then obtained from each recording using a purpose-built hybrid analog/digital computer.[6] The hourly data from all patients were pooled for each consecutive hour of the day, and pre- and post-therapy differences assessed for statistical significance using Student's two-tailed t test on the paired results.

The supine rest, tilt, isometric, and dynamic exercise results were computed using a digitizing program. For supine rest, mean systolic and diastolic BP over 30 beats of each minute in the last 5 minutes was taken. During tilt, mean systolic and diastolic BP over consecutive 15-second periods from the start of the tilt to 1 minute after returning to the supine position, were computed. During isometric exercise, the mean systolic and diastolic BP over 20 beats every 30 seconds was computed and the peak response extracted from this assessment. For dynamic exercise the mean BP over 30 beats at the end of the final minute of each level of exercise was digitized for further analysis. For each test, heart rate values were extracted in the same way as BP. Pre- and post-therapy differences were again assessed using Student's paired t test.

Results

A total of 19 patients entered the study and underwent the first period of intraarterial monitoring. Out of this group, 2 patients were later withdrawn. One was unwilling to undergo the second recording and the other was admitted to hospital because of a small myocardial infarction. The latter patient had been on therapy for 15 weeks and had no history of ischemic heart disease. He made an uncomplicated recovery.

Of the 17 patients who underwent the first (untreated) and second (nifedipine tablets twice daily) intraarterial recordings, 11 were male and 6 female. Their mean age was 54.6 years (range 38 to 65) and their supine clinic BP (after 3 minutes' rest) was 182 ± 15/109 ± 9 (mean ± standard deviation). The mean interval between their recordings was 12.6 weeks (range 8 to 27). The mean dose of nifedipine tablets administered to this group was 80 mg daily.

Out of this group 8 patients consented to a third study while taking their previous total dose of nifedipine once daily in the morning at 8 A.M. One patient's results were not included for analysis because of technical problems (excessive transducer drift). The supine clinic BP of the remaining 7 patients was 186 ± 17.6/107 ± 9.4 (mean ± standard deviation). The mean interval between the second and third recordings was 9 weeks (range 6 to 14), and the mean dose was 80 mg daily.

Circadian variation and BP reduction over 24 hours: Mean hourly values of systolic and diastolic BP and heart rate were obtained consecutively throughout the day to assess the 24-hour profile of BP reduction. Figure 1 shows the group data from 12 noon on the first day of recording to the same time the following day, before and during therapy with nifedipine tablets, twice daily. The circadian variation of BP, which has previously been fully described,[7] is clearly shown.

Although the shape of the curve was unchanged by therapy, there was a substantial reduction in both systolic and diastolic BP throughout the 24-hour period. Within-patient statistical comparisons (paired t tests) showed the reduction in both systolic and diastolic BP to be highly significant ($p < 0.001$) for 23 of the 24 one-hourly periods. The heart rate was not significantly changed by twice-daily therapy throughout the 24 hours.

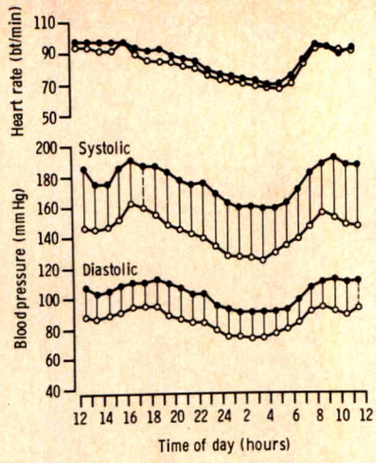

FIGURE 1. Circadian variation of heart rate and systolic and diastolic blood pressure in 17 patients. **Closed circles,** untreated; **open circles,** nifedipine tablets twice daily. Mean hourly differences: **solid lines,** p <0.001; **dashed lines,** p <0.01.

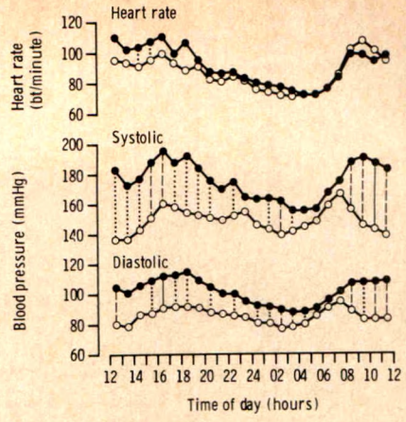

FIGURE 2. Circadian variation of heart rate and systolic and diastolic blood pressure in 7 patients treated with nifedipine tablets once daily (**open circles**). Closed circles, untreated. Mean hourly differences: **solid lines,** p <0.001; **dashed lines,** p <0.01; **dotted lines,** p <0.05.

Once-daily therapy (Fig. 2) produced a very similar profile of BP reduction from 9 A.M. until approximately 6 P.M. In fact, a slightly greater reduction was observed between 12 noon and 4 P.M. with once-daily therapy, although this was not statistically significant. However, between 6 P.M. and 8 A.M. on the following day the efficacy of the single dose was clearly diminished. The 24-hour heart rate profiles were almost identical, except for a small but significant increase in heart rate between 9 A.M. and 11 A.M. on the once-daily therapy.

Physiologic tests: A summary of the results is given in Table I. Fifteen patients provided satisfactory data for analysis; the remaining 2 patients had poor-quality recordings. A third patient was unable to perform dynamic exercise on the bicycle ergometer, so that results for this test were available in 14 patients.

The program began with a period of supine rest during which BP naturally tended to fall. Table I shows the group mean BP values taken from the last 5 minutes of supine rest. After treatment with nifedipine tablets twice daily, both systolic and diastolic BP were further reduced (p <0.001). During head-up tilt to 60°, BP was also significantly reduced by therapy (p <0.001), but there was no additional postural decrease in BP at the beginning of the tilt. Both untreated and treated heart rates increased slightly during the first 90 seconds of tilt. Peak values of systolic and diastolic BP obtained during isometric exercise were significantly reduced by therapy (p <0.001), although the rate of rise and the magnitude of the response was unaltered (Fig. 3).

There was no significant alteration in the peak heart rate response to isometric exercise. Systolic and diastolic BP was uniformly lower with nifedipine during each minute of dynamic exercise. The results are shown in Fig. 4 up to the ninth minute when 8 patients were still exercising. Again, the rate of rise and overall increase in BP was unaltered, and the heart rate response was also unchanged.

Side effects: There were no side effects considered severe enough to necessitate withdrawal from the trial. One patient was withdrawn after 15 weeks of medication because of a myocardial infarction; the circumstances of this were described earlier.

With twice-daily therapy, 3 patients developed ankle edema but had no change in body weight. Two others had flushing of the face and extremities almost 1 hour after each dose. One patient also complained of headaches and giddiness. During the once-daily treatment period 1 further patient developed ankle edema and another had headaches and giddiness.

Discussion

The only consistent hemodynamic abnormality in patients with essential hypertension is increased pe-

TABLE I Intraarterial BP During Physiologic Tests (Mean ± SD)

		Blood Pressure (mm Hg)	
		Before Treatment	After Treatment*
Supine rest (last 5 minutes) (n = 15)	Systolic	175 ± 20.5	141 ± 11.6
	Diastolic	98 ± 11.0	80 ± 8.0
Head-up tilt (60°) (n = 15)			
15 seconds	Systolic	174 ± 18.3	141 ± 17.0

ripheral resistance due to arteriolar vasoconstriction.[8] It is, therefore, logical that slow calcium-channel blocking agents, which relax vascular smooth muscle,[9] should be useful in treating this condition. Nifedipine has been reported to induce dilatation of the resistance vessels without affecting the venous capacitance vessels in normal subjects.[10] Also, a larger decrease in forearm vascular resistance in hypertensive patients than in normal subjects, after acute sublingual administration of nifedipine, has been described.[11]

The results of this study confirm the antihypertensive effects of nifedipine using direct methods of measurement. Furthermore, with the use of continuous ambulatory recording, during which patients have carried on their normal daily activities and slept at home, substantial BP reduction has been shown to occur throughout 24 hours with administration of nifedipine tablets twice daily. Once-daily morning therapy appeared effective for at least 12 hours after administration, after which control became poorer, as might be expected from the pharmacokinetic characteristics of nifedipine tablets.

The degree of antihypertensive activity we observed might be compared with that of beta-adrenoreceptor blocking agents. Similar studies with the latter agents have demonstrated that they may have little effect at night and during the morning period when BP is increasing rapidly.[12] This profile of action cannot be altered by varying the time of administration of the drug, or by using a multiple daily dosage regime instead of once-daily administration.[13] It has been suggested, therefore, that the rapid increase in BP in the morning follows a vasoconstricting sympathetic discharge mediated through alpha receptors in the peripheral arterial system. Although this remains to be proved, the effects of nifedipine, which is a potent vasodilator, contrast strongly with those of beta-adrenoreceptor blocking drugs.

In addition, nifedipine produced significant reduction in BP during the physiologic tests in the laboratory. During supine rest, untreated BP normally tended to decrease slowly to a steady baseline level. However, a further significant reduction in BP was observed with therapy. There was no postural hypotension at the onset of tilting. Absolute peak blood pressure levels were reduced by nifedipine, with no effect on the heart rate response during isometric exercise. These results are important because antihypertensive drugs have generally been disappointing in controlling BP elevations due to isometric exercise.[14] Similarly, absolute BP in response to dynamic exercise on a bicycle ergometer was significantly lower throughout the duration of the test, but there was no effect on the rate of change of BP with increasing work load or attenuation of the overall increase in BP. Comparable effects on BP during isometric and dynamic exercise have been reported with another slow calcium-channel blocking agent, verapamil,[15] and thus it is likely that these agents have no effect on the sympathetic reflexes responsible for these exercise-induced changes in BP.

It was interesting to note that mean hourly heart rate values were not significantly changed by chronic therapy. Acute studies with nifedipine capsules have shown a rapid decrease in BP with a concomitant increase in heart rate and cardiac output,[16] presumably due to a reflex increase in sympathetic activity mediated by the

baroreceptors. Differences between acute and chronic administration may be due to resetting of baroreceptor sensitivity, but it must also be taken into account that baroreceptor influences on heart rate may be short-lasting and have no significant effect on mean hourly heart rates. Other studies of chronic therapy for ischemic heart disease[17] have shown an increase in mean hourly heart rates, but in these studies nifedipine capsules were used, which produce high peak serum levels rapidly after each dose. The tablet formulation is less likely to do this.

Unwanted effects of vasodilator therapy such as increases in plasma noradrenaline or renin activity[18] and retention of sodium and water[19] have been reported; these effects could limit the BP reduction caused by nifedipine. They were not specifically quantified, but it appears from the BP reduction observed that these possible effects had no practical importance within the duration of this study.

In conclusion, therefore, nifedipine in tablet form has been shown to be an effective antihypertensive agent which can provide full 24-hour control with twice-daily dosage in ambulant patients and also maintain significantly lower BP during exercise. These results suggest that this drug may be useful as first-line therapy, although further studies are needed to establish its place in the long-term treatment of hypertension. The currently available nifedipine capsules are unlikely to produce the same results because of their shorter plasma half-life.

INSTRUCTIONS TO AUTHORS

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal*. All accepted manuscripts are subject to editing to aid understanding and conserve space.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

TITLE PAGE, SUMMARY, AND ABSTRACT: Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

REFERENCES: In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

Journal: Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.

Chapter in Book: Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.

Book: Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

FIGURES: Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

TABLES: Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

REPRINTS: Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.

Relation Between Site of Origin of Ventricular Tachycardia and Relative Left Ventricular Myocardial Perfusion and Wall Motion

THOMAS M. McFARLAND, MD, DAVID M. McCARTHY, MD,
P. TODD MAKLER, Jr., MD, and MARK E. JOSEPHSON, MD

To assess the relation between the site of origin of ventricular tachycardia (VT) and relative myocardial perfusion and wall motion, 18 patients with a history of recurrent sustained VT underwent cardiac catheterization, invasive electrophysiologic study with endocardial mapping, and resting radionuclide ventriculography. In addition, 6 patients had exercise and redistribution thallium-201 scintigraphy, whereas the remaining 12 patients had resting thallium scans. The site of origin of VT (determined by catheter and intraoperative endocardial mapping) was correlated with relative myocardial perfusion (thallium) and left ventricular (LV) wall motion. All patients had significant (>50% narrowing) coronary artery disease and 16 had LV aneurysms.

Twenty sites of origin of VT (28 morphologies) were identified in these 18 patients. Of the 9 patients with multiple VT morphologies, the VT originated at disparate sites in 2 patients. All 18 patients had thallium defects at rest and 3 patients had additional reversible (ischemic) defects on exercise. Of the 20 sites of origin of VT, 16 were at the periphery of the thallium defect, 1 was adjacent to it, and 3 were in the center of it. In the 16 patients with LV aneurysm, there were 18 sites of origin: 15 at the border of the aneurysm, 1 adjacent to it, and 2 within it.

The data suggest that in patients with VT and coronary artery disease the site of origin is usually the periphery of a resting thallium defect, and in patients with LV aneurysm the site is the border of the aneurysm.

Recurrent sustained ventricular tachycardia (VT) is a potentially lethal arrhythmia which is commonly associated with coronary artery disease, previous myocardial infarction, and left ventricular (LV) aneurysm.[1–3] Surgical therapy with coronary artery bypass grafting for recurrent VT has met with limited success, and LV aneurysmectomy has frequently failed to cure this arrhythmia.[3–8] More recently, LV aneurysmectomy coupled with endocardial excision at the site of origin of the recurrent VT (as determined by endocardial mapping) has been successful in the treatment of this arrhythmia.[8–11] Observations during LV aneurysmectomy, endocardial mapping, and endocardial excision suggest that VT generally originates at the border of a LV infarct scar.[10,11] To more objectively assess the relation between the site of origin of recurrent VT and relative myocardial perfusion and wall motion, catheter endocardial mapping of the site of origin of recurrent VT was compared with the results of thallium-201 myocardial perfusion scanning, radionuclide ventriculography, and coronary angiography and left ventriculography.

Methods

Patient population: The study population consisted of 18 consecutive patients with recurrent sustained VT (Table I) who underwent endocardial mapping of the VT site of origin and thallium scintigraphy and radionuclide ventriculography. There were 17 men and 1 woman with a mean age of 56 years (range 39 to 73). All patients had significant coronary artery disease, defined as >50% diameter narrowing of a major cor-

onary vessel, and 14 patients had total occlusion of at least 1 vessel. There were 4 patients with 1-vessel, 7 patients with 2-vessel, and 7 patients with 3-vessel coronary artery disease. Sixteen patients had a LV aneurysm at cardiac catheterization. The mean LV ejection fraction was 32% (range 9 to 71%).

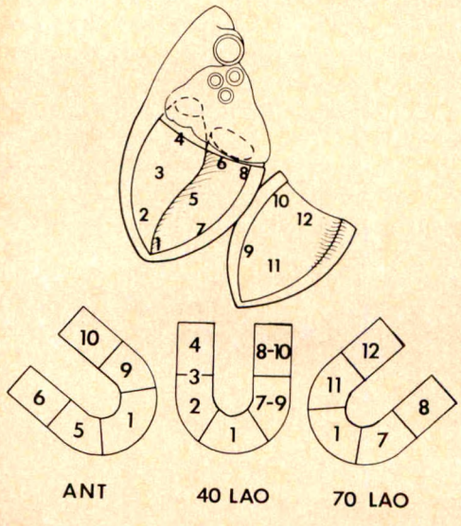

FIGURE 1. Top, schema of the 12 left ventricular endocardial mapping sites. **Bottom,** relation between the 12 left ventricular mapping sites and the thallium-201 scans in the anterior (ANT), 40° (40 LAO), and 70° (70 LAO) left anterior oblique views. See text for details.

Electrophysiologic studies: Electrophysiologic studies were performed in the nonsedated postabsorptive state. In each patient 3 to 6 electrode catheters were inserted either percutaneously or by cutdown and were fluoroscopically positioned in the right atrium, right ventricle, and left ventricle as previously described.[2,12] Programmed stimulation, including incremental ventricular pacing and introduction of 1 to 4 ventricular extrastimuli after every eighth spontaneous or paced beat, was performed with a programmable stimulator (Bloom Associates, Narberth, Pennsylvania). Current was delivered in 1.0 ms impulses at twice the diastolic threshold using an isolated constant current source.

Intracardiac electrograms were displayed simultaneously with 2 or 3 surface electrocardiographic leads on a switch-beam oscilloscope at filter frequencies of 30 to 500 Hz. Care was taken to assure electrical isolation of the patient and equipment. The data were stored on magnetic tape and later retrieved on photographic paper at speeds of 150 to 250 mm/s.

The LV mapping catheter was positioned using the retrograde arterial approach. The 12 preselected LV sites are shown in Figure 1. These sites include the LV apex (site 1), septum (sites 2 to 4), inferior (sites 5 and 6), inferolateral (sites 7 and 8), anterolateral (sites 9 and 10), and anterior walls (sites 11 and 12). When an aneurysm was present, mapping from the endocardial surface of the aneurysm was attempted. Catheter position was verified by fluoroscopy in multiple planes. Data were obtained by recording endocardial electrograms using an electrode catheter with a 1 cm interelectrode distance. Once the VT was initiated, endocardial mapping of the VT was performed.[12,13] Activation mapping from all 12 LV sites was obtained. Ventricular activation time at each LV site was determined by comparison with the right ventricular reference electrogram and the onset of the surface QRS complex. The

VT site of origin was defined as the site with the earliest activation. The accuracy of the activation mapping has been confirmed with intraoperative mapping of VT.[13,14]

Cardiac catheterization and contrast ventriculography: All patients underwent cardiac catheterization and selective coronary angiography by either the Sones or the Judkins technique. Left ventriculography was performed in the standard 30° right anterior oblique projection in all 18 patients, and a second ventriculogram in the 45° to 60° left anterior oblique projection was performed in 12 patients. The ventriculogram was analyzed by the area-length method in the right anterior oblique view for ejection fraction, and was studied qualitatively for LV asynergy including akinesis, hypokinesis, or dyskinesis.

Thallium-201 myocardial imaging: Resting thallium-201 imaging was performed in 12 patients who were deemed unable to exercise due to either poor LV function or recent femoral arterial catheterization or both. Left ventricular ejection fraction in these patients was significantly lower than that in the 6 patients who were able to exercise (27 versus 43%, $p < 0.02$). After injection of 1.5 to 2.0 mCi of thallium-201 chloride, images were recorded in the anterior, 40°, and 70° left anterior oblique views using a single crystal gamma camera (Picker Dynamo) interfaced to a dedicated nuclear medicine computer (DEC Gamma-11).

Exercise and redistribution thallium-201 imaging was performed in the 6 patients who were judged capable of performing an exercise test. The exercise test was performed on a treadmill using a modified Bruce protocol, and exercise was continued until the patient experienced anginal pain, fatigue, or lightheadedness. No patient had ventricular arrhythmia during exercise. Thallium-201 chloride (1.5 to 2.0 mCi) was injected approximately 1 minute before termination of exercise. Imaging began 10 minutes after the injection of tracer during exercise and was repeated 4 hours later for the redistribution scan. Images were acquired in the anterior, 40°, and 70° left anterior oblique views.

Radionuclide ventriculography: Radionuclide ventriculography was performed on a separate day by the equilibrium technique using red blood cells labeled in vivo with 20 mCi of technetium-99m pertechnetate.[15] All studies were performed during sinus rhythm with the patient supine, using a single crystal gamma camera. Scans were collected in the anterior and 45° and 70° left anterior oblique views. Ejection fraction was calculated from the 45° left anterior oblique scan.

Relation between a site of origin of VT and thallium scans: The relation between the 12 LV mapping sites and the thallium scans is shown in Figure 1. Each scan view was divided into 5 zones, and the perfusion defects were related to these zones. The scan graders were unaware of the results of endocardial mapping. Each scan zone correponds to 1 or more LV mapping sites. The site of origin of VT was said to be the *center* of a thallium defect if the scan zone corresponding to the site of origin and the scan zones of all contiguous mapping sites were involved by the defect. Ventricular tachycardia was said to originate at the *periphery* of a scan defect if the corresponding scan zone was involved by the defect but at least 1 contiguous mapping site was not involved in the defect. Finally, VT was said to come from a region *outside* a defect if the scan zone corresponding to the site of VT was not involved by the defect.

Relation between site of origin of VT and LV wall motion: Wall motion was elevated by 2 observers who were kept unaware of the other results. The extent of focal wall motion abnormality (akinesia or dyskinesia) was determined by superimposing the end-diastolic and end-systolic perimeters of the radionuclide ventriculogram with each view being divided into 5 regions (Fig. 2). Left ventricular wall motion also was assessed by contrast ventriculography. The results of both of these methods correlated well (Table I) and were both used to define the presence and location of LV aneurysms. Left ventricular ejection fraction using both methods correlated closely ($r = 0.82$).

Large regions of discrete LV akinesia or dyskinesia were interpreted as indicating the presence of a LV aneurysm. The site of origin of recurrent sustained VT as determined by endocardial mapping was then compared with LV wall motion, using the relation shown in Figure 2. In patients with a LV aneurysm, the site of origin of VT was assessed as to whether it was on the border, in the center, or outside of the LV aneurysm, using a similar schema as with the thallium-201 scans.

Results

There were 28 morphologically distinct VT in the 18 patients, and these were localized to 20 sites of origin (Table I). In 2 patients (Patients 13 and 15) with 2 VT morphologies each, the origins occurred at disparate sites. Ten sites of origin of VT involved the septum of the left ventricle, 6 sites of origin the inferior region of the left ventricle, and 4 sites of origin the superior LV free wall.

All 18 patients had abnormal thallium scans at rest or redistribution (fixed defects), and 3 of the 6 patients with exercise scans had additional (ischemic) defects on exercise. The peak heart rate of the 3 patients with ischemic defects on exercise was 83% of predicted maximum versus 64% for the 3 patients who did not demonstrate ischemic defects with exercise. Of the 20 sites of origin of VT, 16 were the periphery of the fixed defect and 3 were the center of the fixed defect. In only 1 patient (Patient 17) was the site of origin of VT thought to be outside the fixed thallium defect. In the 3 patients with additional ischemic perfusion defects on exercise, the site of origin of VT was located in the fixed (redistribution) defect and not in the reversible (ischemic) defect.

Sixteen of the 18 patients had a LV aneurysm. Of the 18 sites of origin of VT in these patients, 15 were thought to be the border of the aneurysm and 2 within the aneurysm. In only 1 patient (Patient 17) was the site of VT thought not to be the border or within the aneurysm, and in that 1 patient the site of VT was adjacent to the aneurysm.

Figure 3 shows the results in a 39-year-old man (Patient 10) with a history of anteroseptal and anterolateral myocardial infarction and recurrent sustained VT. All 3 views of the resting thallium scan show extensive scar,

FIGURE 2. Relation between the 12 left ventricular mapping sites (see Fig. 1) and the radionuclide ventriculograms in the anterior (ANT), 45° (45 LAO), and 70° (70 LAO) left anterior oblique views. See text for details.

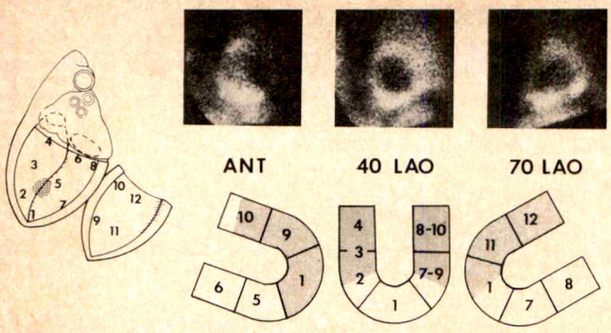

FIGURE 3. Resting thallium-201 scans (**right**) in Patient 10. The location of the perfusion defects is indicated schematically below the scans. The patient's ventricular tachycardia originated at the junction of the mid-septum and the inferior wall, shown by the stippling on the schema (**left**). See text for details.

with the defect indicated schematically below. The earliest site of ventricular activation during VT in this patient was the point at which the mid-septum meets the inferior wall (between sites 2, 3, and 5) and is depicted by stippling on the schematic mapping diagram in the illustration. The site is the periphery of the thallium defect, since the scan defect involves sites 2 and 3 (septum) but not site 5 (the contiguous site). The site of origin of VT was also the border of an anterior aneurysm seen on both the radionuclide and the contrast ventriculogram.

Discussion

The mechanism of recurrent sustained VT in man is believed to be reentry from a relatively small and protected region of the heart.[2,16,17] Catheter mapping suggests that reentry takes place at or near the endocardium.[12,16,17] Epicardial mapping has previously been used as a guide to surgical therapy for recurrent sustained VT; however, studies in both animals and man show that the endocardial site of origin of VT may be distant from the site of epicardial electrical breakthrough.[14,18] Early surgical results of endocardial mapping and endocardial excision have been encouraging.[8–11] Observations during LV aneurysmectomy, endocardial mapping, and endocardial excision have suggested that the site of origin of recurrent VT is generally the border of a LV myocardial infarction scar.[10,11]

Limitations of methods: The accuracy of endocardial catheter determination of the site of origin of recurrent sustained VT has previously been validated with intraoperative endocardial mapping.[13,14] Endocardial catheter mapping of VT can predict the site of origin of VT within 4 to 8 cm^2 of that determined by intraoperative endocardial mapping.[9,10,13] Furthermore, the accuracy of endocardial catheter activation mapping in this study was confirmed with intraoperative mapping during sustained VT in 16 of the 18 patients.

Left ventricular wall motion was analyzed by both radionuclide ventriculography and contrast ventriculography, with good correlation of wall motion and ejection fraction by both methods. This finding is in agreement with those of previous studies.[19] The complementary use of these methods provided good identification and localization of LV aneurysms, as expected from previous reports.[20]

The analysis of myocardial perfusion in this study was obtained from the results of thallium-201 myocardial scintigraphy, which provides a visual representation of the relative distribution of myocardial blood flow. In this group of patients, resting or redistribution thallium-201 myocardial perfusion scans revealed relatively large defects associated with previous myocardial infarctions which were suspected from the patients' histories and electrocardiograms. Thallium defects reflect both the site and the location of myocardial infarction,[21,22] although small infarcts (<7 g) may not be identified.[23] Phantom studies[24] have shown that defects as small as 1.5 cm in diameter can be detected, although defects are probably more easily identified in a phantom study than in a patient.[23] The consistent finding that the site of origin of VT is the periphery of the thallium scan defect and the border of the LV aneurysm lends further support to the reliability of the method.

Exercise-induced perfusion abnormalities: To assess the possible correlation between myocardial ischemia and the site of origin of recurrent VT, exercise thallium-201 myocardial perfusion scanning was performed in those patients who were judged capable of exercising. Only 6 of the 18 patients were able to undergo thallium-201 exercise myocardial perfusion scanning, and of these 6 patients, only 3 patients had reversible perfusion defects with exercise. In these 3 patients, 3 of the 4 sites of origin of VT were the periphery of the fixed defect. Importantly, VT was induced by programmed extrastimuli in the *absence* of ischemia, and the development of ischemia during exercise was *not* associated with the appearance of VT. Although the number of patients is small, these results suggest that ischemia may not be a major factor contributing to recurrent VT in these 3 patients. This impression is further supported by a recent preliminary report in which 25 patients with recurrent sustained VT underwent treadmill testing and only 2 of the 25 patients developed VT on exercise.[25]

Pathophysiology: The finding that the site of origin of recurrent VT is the periphery of a myocardial infarction scar is consistent with the requirement that a segment of tissue that is electrophysiologically excitable be adjacent to one of slow conduction. Myocardial infarction scar tissue is typically associated with abnormal conduction.[26,27] The border zone of the myocardial infarction scar has a heterogeneous transition zone from homogeneous fibrous scar tissue to normal myocardium, and thus provides an electrophysiologic substrate for the origin of dysrhythmia. Preliminary data suggest such an anatomic substrate.[28] Because 16 of the 18 patients with recurrent VT had a LV aneurysm involving the site of a previous large myocardial infarction, increased wall tension in the border zone of the LV aneurysm may also have a role in producing recurrent VT.

Clinical implications: The results of this study support the intraoperative observations that the site of origin of recurrent VT generally is the border of a LV

aneurysm or the periphery of a LV myocardial infarction scar.[10,11] These results help to explain previous limited surgical success in the treatment of recurrent VT by coronary artery bypass grafting and LV aneurysmectomy, because LV aneurysmectomy usually does not remove the border region of the LV aneurysm, particularly in patients with VT arising from the ventricular septum. Thus, the present study provides noninvasive support for endocardial excision of the site of origin as an essential component in the surgical treatment of recurrent VT.

Acknowledgment: We thank Geri McCausland for preparation of this manuscript, Rita Falcone for assistance with the illustrations, and Drs. Scott Spielman and Harvey Waxman for their comments. We are especially grateful to Dr. Leonard Horowitz for his suggestions regarding the correlation of endocardial mapping sites with thallium-201 scan zones.

Ultrarapid Single-Capture Train Stimulation for Termination of Ventricular Tachycardia

JOHN D. FISHER, MD, ELIOT OSTROW, BS,
SOO GYUM KIM, MD, and JEFFREY A. MATOS, MD

Termination of ventricular tachycardia (VT) with single programmed extrastimuli or slow underdrive competitive pacing is often possible. The usefulness of these techniques is limited because the zone in the cardiac cycle during which programmed stimuli are effective may be narrow, with significant time elapsing until termination of the VT, and the zone may vary markedly between episodes, rendering preset extrastimuli ineffective. Ultrarapid trains of stimuli beginning during the refractory period and of a duration sufficient to cause only a single capture should terminate all tachycardias whose termination zone begins just after the refractory period. To test this hypothesis, 21 patients with 371 well-tolerated episodes of VT had single programmed extrastimuli and trains of 10 bipolar stimuli at 25, 50, and 100 Hz. VT was terminated 1 or more times in 18 of the 21 patients with programmed extrastimuli or trains, or both. Forty-eight percent of 290 episodes were terminated with programmed stimulation, compared with 56% of 120 episodes with trains (difference not significant). In 98 episodes, the effects of trains and programmed stimulation could be matched (same patient, date, tachycardia morphology, rate, and drug therapy); the results were concordant (both techniques either terminated the VT or failed) in 92 and discordant in 6. With only 2 possible exceptions, the termination zone always began just after the refractory period; thus, for tachycardias terminating with single captures, the first train to achieve capture was effective, minimizing the duration of the VT.

Ultrarapid train stimulation at rates equivalent to several thousand beats per minute, but with the duration of the train limited to achieve only a single capture, has been used with high stimulus amplitudes in the study of ventricular fibrillation thresholds[1,2] and at lower amplitudes for the termination of supraventricular tachycardias.[3] Termination of ventricular tachycardia (VT) with single programmed extrastimuli is often possible[4–8] but is of limited use in implantable pacemakers because the zone in the cardiac cycle in which programmed stimulation is effective (termination zone or window) may be narrow with significant time elapsing until termination; and the zone may vary daily,[8] rendering preset[6,7] extrastimuli ineffective. However, if the termination zone begins just at the end of the refractory period, train stimulation at 50 to 100 Hz beginning in the refractory period, and of a duration causing a single capture, should terminate all susceptible tachycardias, unaffected by changes in the timing and duration of the termination zone (Fig. 1). The present study tests this hypothesis, and determines whether high-frequency train stimulation might be useful in the termination of VT.

Methods

Twenty-one patients undergoing serial electrophysiologic testing for control of recurrent VT were studied. Patients were selected for participation in the train stimulation study if the VT was sufficiently well tolerated to permit detailed testing with the extrastimulus technique and with train stimulation.

The 21 patients included 16 with coronary artery disease, 2 with dilated cardiomyopathy, and 1 each with mitral valve prolapse, arrhythmogenic right ventricular dysplasia, and no demonstrable heart disease. There were 15 men; ages ranged between 18 and 78 years (mean 58).

After induction of VT and establishment of hemodynamic stability, attempts at termination were begun. Single programmed extrastimuli or 100 Hz train stimulation were used as described later, in alternating sequence for successive episodes or termination attempts. Programmed stimulation was initiated beginning within the refractory period (130 to 150 ms after sensing of the VT beat) and moving later in 10 ms steps. Programmed extrastimuli were given every eighth beat, and continued until termination of the VT, or until the entire diastolic period was scanned. Similarly, during established VT, trains of 10 bipolar stimuli were delivered every eighth VT beat, beginning in the refractory period. Intervals between successive stimuli in the train were 10 ± 2 ms (100 Hz, 6,000 beats/min) in all 21 patients. Trains with intervals approximating 20 and 40 ms (50 and 25 Hz) were subsequently used in 17 and 11 patients, respectively, and 3 to 5 ms interval trains were used in 3 subjects.

Programmed extrastimuli and train stimulation used in the attempted termination of the VT were provided by a Savita Orthorhythmic® pacemaker. This device is designed to sense with the stimulating catheter, using typical pacemaker type signal processing. The unit is powered by 2 large capacity

batteries. Stimulus amplitudes remained constant during trains at up to 10 mA, and from 11 to 14 mA the delivered stimulus amplitude decreased by a maximum of 15% by the last stimulus in the train. In 4 patients, the stimulus amplitude was set at 4 times diastolic threshold; in the remainder, all stimuli were delivered at 10 to 14 mA, representing >4 times threshold.[9] Each stimulus was 1 ms in duration. The same settings were used for extrastimuli and for trains in each patient.

For 100 Hz trains, the first stimulus was delivered with a delay of 50 ms after sensing of the QRS complex, with the resulting train therefore covering the zone from 50 to 150 ms (always within the refractory period in these patients). Thereafter, the timing of the train was delayed by an additional 10 ms after every eighth VT beat, until capture was obtained or diastole was scanned. With 50 and 25 Hz trains, stimulation began simultaneously with sensing of the QRS complex. Some 50 Hz trains ended within the refractory period, and in such cases the timing was sequentially delayed as for 100 Hz trains.

In patients with easily reproducible VT, the effects of programmed stimulation and train stimulation were confirmed over several trials. The outer limit of the termination zone was established with use of programmed stimulation beginning late in diastole and then with increasing prematurity in 10 ms steps. During testing for reproducibility of termination, the timing of 100 and 50 Hz trains was set to exceed the refractory period by 30 to 40 ms. In comparing trains of different frequency, 100 Hz trains were used first, followed by 50 and 25 Hz.

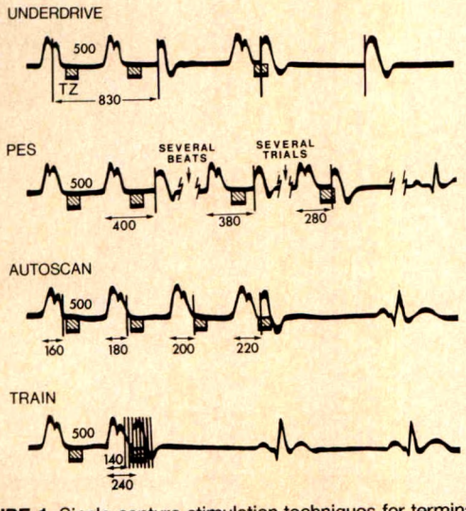

FIGURE 1. Single-capture stimulation techniques for termination of VT. In each panel, VT with a cycle length of 500 ms is illustrated schematically, with the termination zone (TZ) represented by the **hatched box** following the QRS complex. **Top panel,** underdrive. Pacing stimuli appear asynchronously at an arbitrary 830 ms, eventually capturing during the termination zone. This technique is highly inefficient if the termination zone is narrow, or if the tachycardia is poorly tolerated. Further, if the tachycardia rate is a multiple of the underdrive pacing rate, stimulation may occur isorhythmically, never hitting the termination zone. **Second panel,** programmed electrical stimulation (PES). Programmed extrastimuli are inserted every several beats, with their timing altered with respect to the previous QRS complex. Systematic stimulation throughout the diastolic period will ultimately find the termination zone. Programmed extrastimuli are usually begun late in diastole, and then with regularly increasing prematurity. In the present study, the extrastimuli were begun during the refractory period, with subsequent incremental delays. **Third panel,** autoscan. Several varieties of automatic scanning pacemaker techniques have been described. In this variation, the extrastimulus is begun during the refractory period and each QRS complex is followed by a slightly more delayed extrastimulus, until the termination zone is reached. **Bottom panel,** train stimulation. A train is initiated during the refractory period, with the duration sufficient to result in a single capture. Because the tachycardia termination zone begins at the end of the refractory period, termination occurs with the first train.

Refractory periods were measured from recordings made at a paper speed of 100 ms by an Electronics for Medicine VR6 or VR12, or by an Elema Mingograf. The following definitions were used: V_1 = VT beat; V_2 = programmed extrastimulus; and V_{11} = final stimulus in a 10 stimulus train. The effective refractory period was the longest V_1-V_2 or V_1-V_{11} failing to capture.

The functional refractory period was equal to the shortest attainable interval between V_1 and the beat resulting from V_2 or V_{11}. Capture could occur in the midst of a train (typical for 25 and 50 Hz trains and during testing of reproducibility with 100 Hz trains). The functional refractory period was then estimated by measuring from landmarks (Fig. 2, B and D) on the stimulated QRS complexes, and comparing the timing of these with similar landmarks in beats produced by a single extrastimulus at the shortest V_1-V_2 resulting in capture.

When possible, episodes of VT "matched" for date, medications, rate, morphology, and so on were compared. For refractory periods, effective refractory periods were used if available; if not, functional refractory periods from both extrastimuli and trains were compared.

The relative effectiveness of programmed stimulation and train techniques were compared using chi-square analysis. The refractory periods obtained with programmed and train stimulation were compared using a paired t test in episodes matched for patient, date, tachycardia morphology, rate, and medications.

Results

Three hundred seventy-one episodes of VT were studied; the number of episodes was 3 to 82 per patient. Three to 10 episodes were studied in 8 patients, 11 to 20 episodes in 6 patients, 21 to 30 episodes in 4 patients, and ≥34 episodes in 3 patients. VT rates were 106 to 171 beats/min, with a mean of 124 (cycle length 484 ms).

Relative efficacy of programmed stimulation and trains (Fig. 2 and 3): There were 98 matched episodes (same patient, date, VT morphology, and medications) for direct comparison of the extrastimulus and train techniques. There was a concordant response in 92 of these episodes: 38 could not be terminated by programmed stimulation or trains, and 27 were terminated by programmed stimulation and 27 by trains. There was a discordant response in only 6 episodes, 4 of which were terminated by trains but not programmed stimulation, and the reverse for the remaining 2 episodes. Overall, 139 (48%) of 290 episodes were terminated by single programmed extrastimuli, and 67 (56%) of 120 episodes by trains (difference not significant). The total number of episodes appears to exceed 371 because some individual episodes were treated with both programmed extrastimuli and trains.

When trains were used for successive episodes, the train was timed to straddle or bracket the previously determined refractory period, so that 20 to 30 ms fluctuations in the refractory period would be encompassed. On similar reproducibility trials with programmed extrastimuli, the greater time required for termination was often dramatic (Fig. 3).

Thirty-two pairs of refractory periods from pro-

grammed and train stimulation were compared in matched VT episodes in 20 patients. The refractory periods with trains (333 ± 112.5) were found to be 11 ms longer ($p < 0.02$) than with single extrastimuli (322 ± 110). Because the time from onset of VT to termination could not be controlled, it is not clear whether the differences in refractory periods were due to the stimulation techniques themselves, or to secondary changes (such as changes in autonomic tone related to the duration of the arrhythmia).

With both programmed stimulation and trains, the termination zone, when present, began immediately after the effective refractory period, with only 2 possible exceptions outlined in the next paragraph. The duration of the termination zone was assessed in 20 episodes from 11 subjects using the single extrastimulus method. The termination zone varied from 0 to 300 ms (mean ± standard deviation 91 ± 70). A value of zero was recorded when termination was possible only at a single setting established by 10 ms steps, as described in the Methods section.

Comparison among 100, 50, and 25 Hz trains: Among 18 patients tested, the responses to 25 or 50 Hz trains were found to be concordant with those of 100 Hz

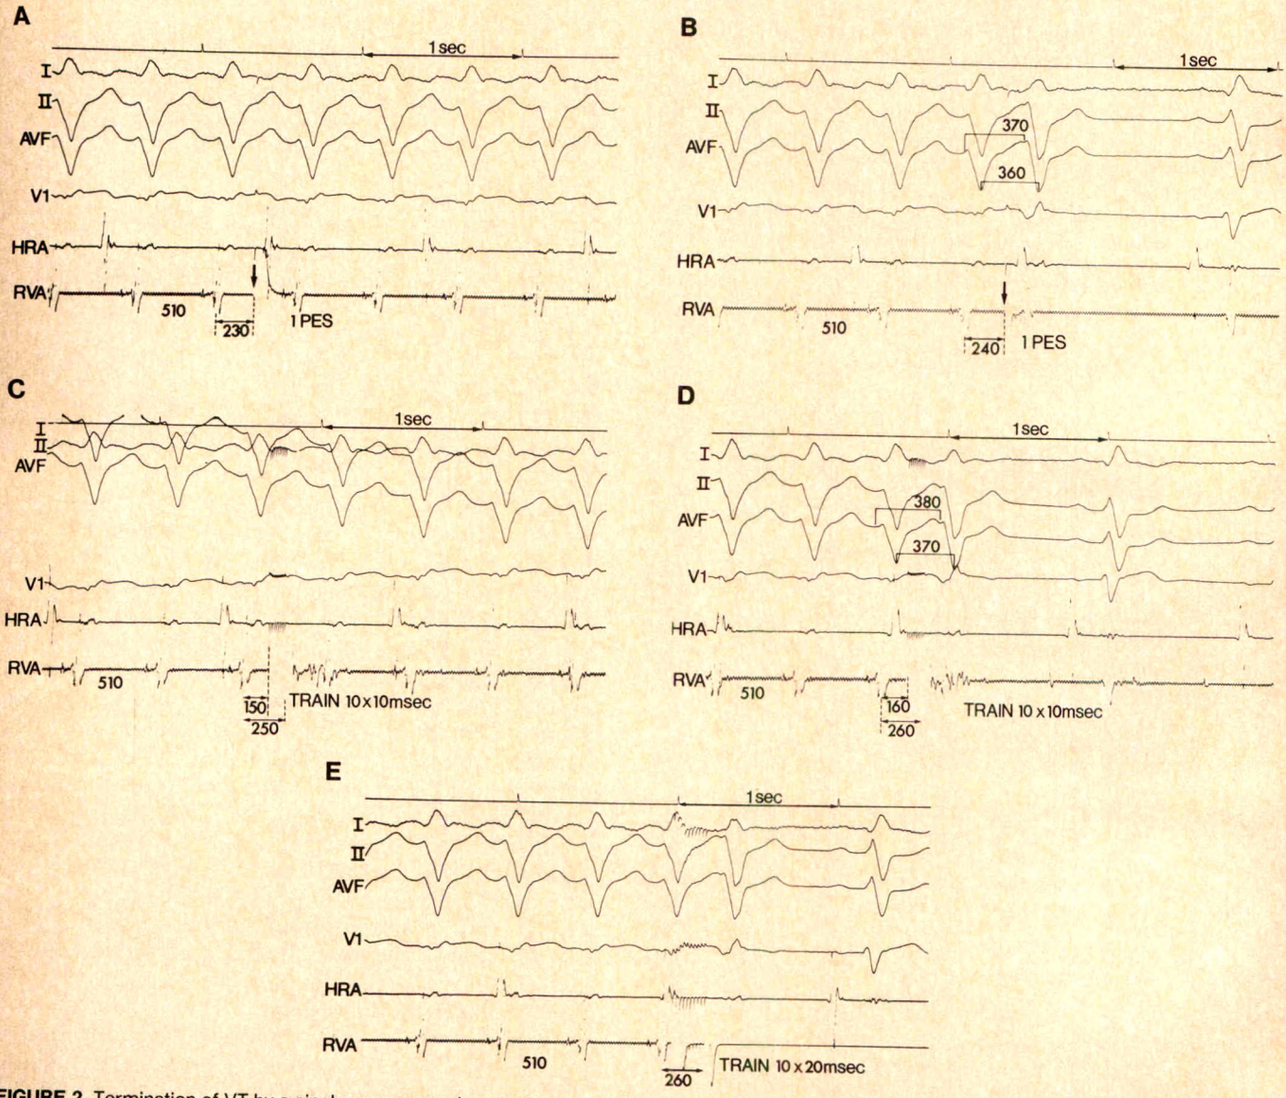

FIGURE 2. Termination of VT by a single programmed extrastimulus (PES) and train stimulation. These illustrations are taken from the same patient, during "matched" episodes of VT as described in the text. In each, the format is the same, with peripheral leads I, II, AVF, and V_1 displayed, together with electrograms from the high right atrium (HRA) and the right ventricular apex (RVA). **A,** a single PES 230 ms after sensing of the QRS complex fails to capture the ventricle. **B,** a single PES delivered 240 ms after sensing of the QRS complex captures the ventricle and terminates the tachycardia. The measurements shown in AVF illustrate the type of "landmarks" used to estimate refractory periods with 20 and 40 ms (50 and 25 Hz) trains (see text). **C,** a 10 ms (100 Hz) train begun with a delay of 150 ms after sensing of the QRS complex fails to capture the ventricle. **D,** the delay of the train is increased to 160 ms, with capture of the ventricle and termination of the tachycardia. The settings on the stimulator, and measurements from both the right ventricular apex and the landmarks in AVF measured in **B** all confirm the refractory period and the termination zone with trains beginning approximately 10 ms later than with PES. **E,** a 20 ms (50 Hz) train began 60 ms after sensing of the QRS complex, and terminates the tachycardia in a fashion similar to that observed with PES and 10 ms (100 Hz) trains. These tracings were all recorded during serial antiarrhythmic trials several days after the initial study. Tachycardias of a similar configuration were observed during the initial study, and His bundle potentials were not observed before the QRS complex, nor was there other evidence to suggest a diagnosis other than VT. The small deflection before the right ventricular apex complex may represent bundle branch activity, "fractionation," or far-field effects.

trains in 44 matched episodes (Fig. 2, D and E) and discordant in 4: 2 were terminated by 100 Hz, but not 50 or 25 Hz trains; 1 episode unresponsive to 100 Hz trains was terminated by a 50 Hz train; and 1 episode unresponsive to programmed stimulation, as well as 100 and 50 Hz trains, was terminated by a 25 Hz train. Whether these were due to fluctuations in the termination zone or other factors related to prior stimuli (see later) is uncertain. Three of the 18 patients also received trains with a cycle length of 3 to 5 ms (330 Hz, 200 Hz)

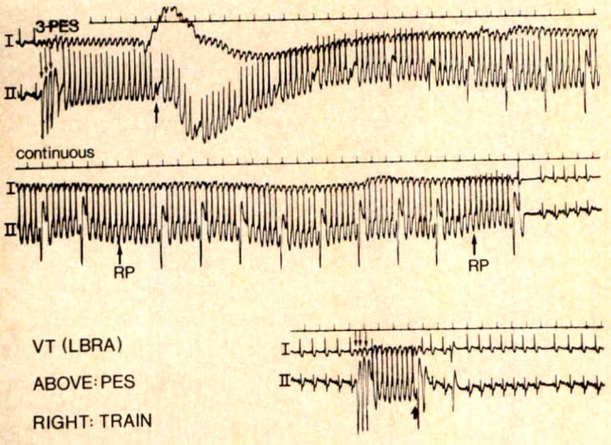

FIGURE 3. Programmed stimulation and trains contrasted. Peripheral leads I and II are displayed along with 1 second time lines. Ventricular tachycardia (VT) of a left bundle right axis morphology (LBRA) is induced by triple programmed extrastimuli (PES), indicated by the 3 **small downward-pointing arrows.** The **top 2 panels** represent a single episode. Attempts to terminate with use of a single PES begin at the **large upward-pointing arrow.** These episodes were recorded in a patient studied after those patients reported on in the present study and incorporate minor changes in the protocol based on lessons learned. The PES are given after every sixth beat, with 20 ms decrements until the effective refractory period (RP) is reached. At that point, the PES is delayed by 40 ms, and then moved once again toward the refractory period in 10 ms steps. The refractory period is not reached for the second time until the ninth stimulus, because of operator inertia and the few seconds required to reset the controls. The tachycardia is finally terminated by an extrastimulus 10 ms beyond the effective refractory period. Time from induction to termination of tachycardia was 70 seconds. **Lower panel,** an identical tachycardia is induced, and terminated by the first 100 Hz train within 4 seconds. The orthorhythmic pacer is limited is 10 stimuli per train. A more flexible device able to generate 15 stimuli would have reached the refractory period (and potential termination zone) of all tachycardias observed in this series with an interstimulus interval of 10 ms and a delay of 150 ms after the previous QRS complex.

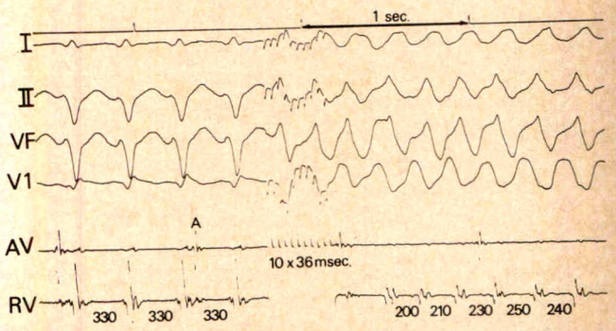

FIGURE 4. Acceleration of VT by a train resulting in 2 captures. Format as in Figure 2. A train with an interstimulus distance of 36 ms is initiated late enough so that 2 ventricular captures result, and accleration ensues. During this study, 20 and 40 ms (50 to 25 Hz) trains were usually initiated with minimal delay after the QRS complex to avoid double capture. AV = lead recording low right atrium and right ventricular inflow; RV = right ventricle.

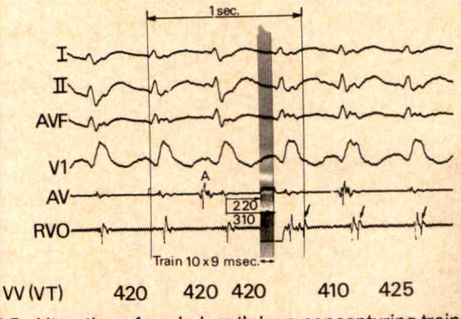

FIGURE 5. Alteration of cycle length by a noncapturing train. Format as in Figures 2 and 4. Ventricular cycle lengths during ventricular tachycardia (VV) (VT) are recorded at the **bottom** and were stable. After 3 regular complexes, an apparently ineffective train is followed by transient alterations in the cycle length, suggesting the possibility that some local capture or fusion did in fact occur. A = atrial depolarization; RVO = right ventricular outflow. Other abbreviations as in Figure 4.

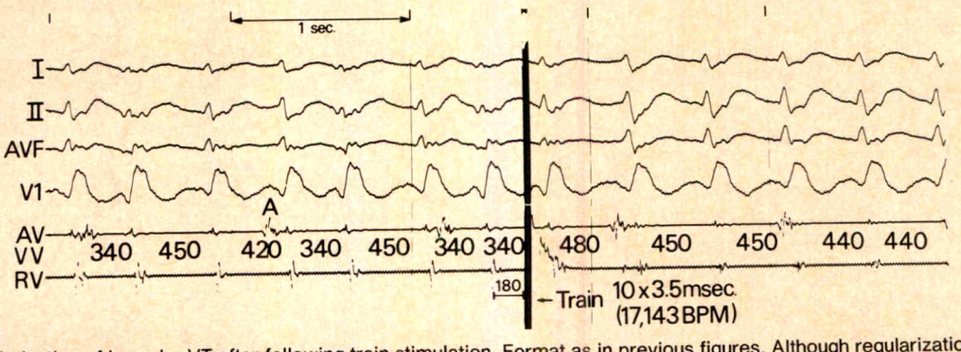

FIGURE 6. Regularization of irregular VT after following train stimulation. Format as in previous figures. Although regularization of a tachycardia may occur spontaneously, its appearance after an otherwise apparently ineffective train once again suggests the possibility of localized depolarization. This patient had tachycardias of several morphologies, with differing initial sites of ventricular depolarizations as determined by intracardiac mapping studies. There were instances of apparent "simultaneous VT"; the illustrated episode (not mapped) may have been such a multitachycardia as judged by the varying morphology of the complexes in leads I and II. One interpretation of the observed changes would be that the train terminated 1 of these tachycardias, regularizing both the cycle length and the morphology. BPM = beats per minute; other abbreviations as in Figures 4 and 5.

during 17 episodes, with results concordant with 100, 50, and 25 Hz trains.

Three episodes of VT were accelerated by train stimulation. Two occurred with a 25 Hz train (10 × 40 ms = 400 ms duration), which resulted in 2 captures (Fig. 4); 1 episode required direct-current cardioversion; the other was unsustained. One episode was accelerated by a 100 Hz train, and 1 by a single programmed extrastimulus. Overall, only 2 (0.54%) of 371 episodes of VT were accelerated by single-capture stimulation.

Other observations: Programmed and train stimulation failed to achieve capture during 7 episodes of VT, despite an adequate threshold margin before and after the episode and successful termination by conventional burst pacing[10] (Fig. 5 and 6). These figures also illustrate the possibility that train stimulation without capture may exert electrophysiologic effects. In Figure 5, the cycle length of a regular VT is altered, and in Figure 6 (the same patient as in Figures 4 and 5), the irregular tachycardia becomes regular after an otherwise ineffective train. In other episodes, the noncapturing train had no effect on cycle lengths.

Discussion

Ultrarapid single capture train stimulation for termination of VT offers several potential advantages. Because the termination zone begins at or very near the end of the refractory period, trains beginning within the refractory period and of a duration calculated to result in a single capture should immediately terminate susceptible VT, despite any changes in refractory periods from day to day or under various metabolic or antiarrhythmic drug conditions.[8]

The risks of acceleration with single capture stimulation (0.54% in this series) appear smaller than those with multicapture techniques.[8–11] Nevertheless, ventricular stimulation in patients with ventricular arrhythmias must always be approached with caution and respect. The potential hazards of train stimulation are evident from its heritage as a test of ventricular fibrillation thresholds,[1,2] and in this study 2 episodes were accelerated by trains of sufficient duration to cause 2 captures. Most VT susceptible to single-capture termination is rather slow (124 beats/min in this series).[8] Faster VT often requires multicapture stimulation methods for termination, with an attendant increase in risk of acceleration.

"Underdrive pacing" in which asynchronous pacer stimuli are delivered randomly during VT[12] may require considerable time for termination of susceptible tachycardias. Automatic "scanning" pacemakers[5–7] deliver programmed extrastimuli in an orderly fashion, but may still require multiple trials. Even pacers with a "memory"[6,7] for the timing of effective stimulation are problematic if the termination zone is narrow and changes significantly from day to day.

As judged from single programmed extrastimuli, the termination zone when present begins immediately after the refractory period. Whereas this was almost always true for train stimulation, there were 2 episodes in which 25 or 50 Hz trains terminated the arrhythmia, while 100 Hz trains were ineffective. In 1 of these episodes, single programmed extrastimuli had also failed to affect the tachycardia. Spontaneous alterations in threshold or tachycardia zone may have played a role in these anomalies, but effects of stimulation during the refractory period have been recognized since 1926.[13,14] More recent work has identified a variety of responses to single, multiple, and train stimulation within the refractory period, with complex interpretations related to summation, inhibition, temporal dispersion of refractoriness,[15] and electrotonic interactions.[16]

The data from this study indicate (1) the termination zone for VT susceptible to single capture termination almost always begins at the end of the effective refractory period; (2) the refractory period averages 11 ms longer with trains than with programmed stimulation, implying an effect of stimulation delivered during the refractory period; (3) programmed stimulation and ultrarapid train stimulation are equally effective in terminating VT; and (4) trains are more efficient than programmed stimulation for termination of a susceptible VT, because the arrhythmia will usually be terminated with the first capture and because the effectiveness of given train parameters is not altered by changes in the timing or duration of the termination zone.

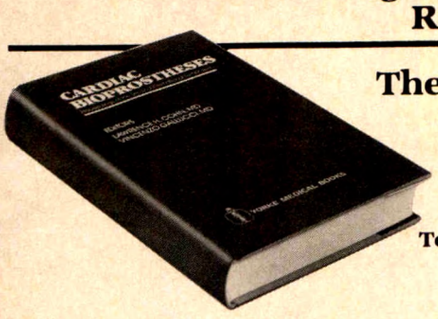
Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982



The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

To order your copy of this important new book use the order form below.

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today.*

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology,* now available in its second issue, *Cardiology 1982.*

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

Table of Contents

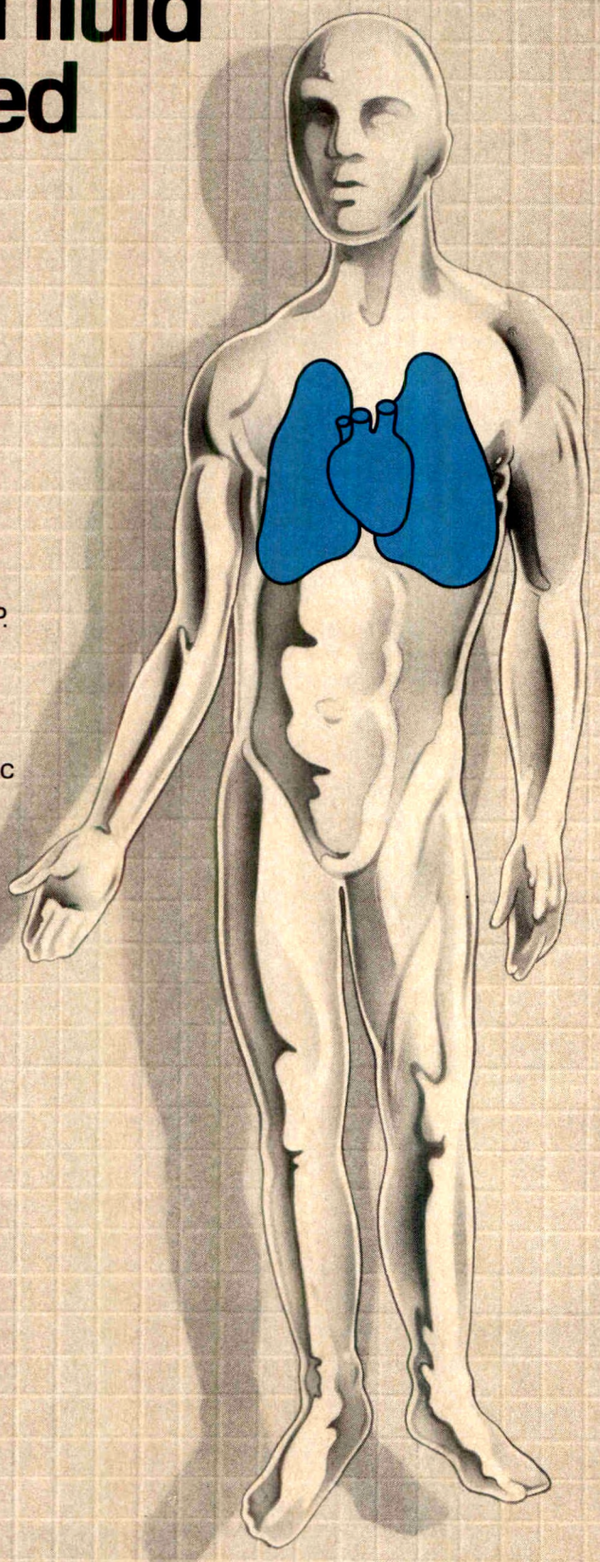
Therapeutic challenge:

Redistribution of fluid in CHF associated with acute MI



In Early CHF[1]

Pulmonary congestion with increased preload.

Findings: Elevated preload, elevated blood pressure, normal or slightly decreased cardiac output, PCWP greater than or equal to 18 mm Hg.

Therapeutic goal:
Reduce pulmonary congestion, lower PCWP to 15 to 18 mm Hg.

In Late CHF[1]

Pulmonary congestion with increased preload and afterload.

Findings: Low cardiac output, depressed blood pressure, and high PCWP.

Therapeutic goal:
Reduce pulmonary congestion, preload, and afterload, increase cardiac output, and lower PCWP to 15 to 18 mm Hg.

Why wait for the patient to become unresponsive to traditional diuretic/digitalis therapy?

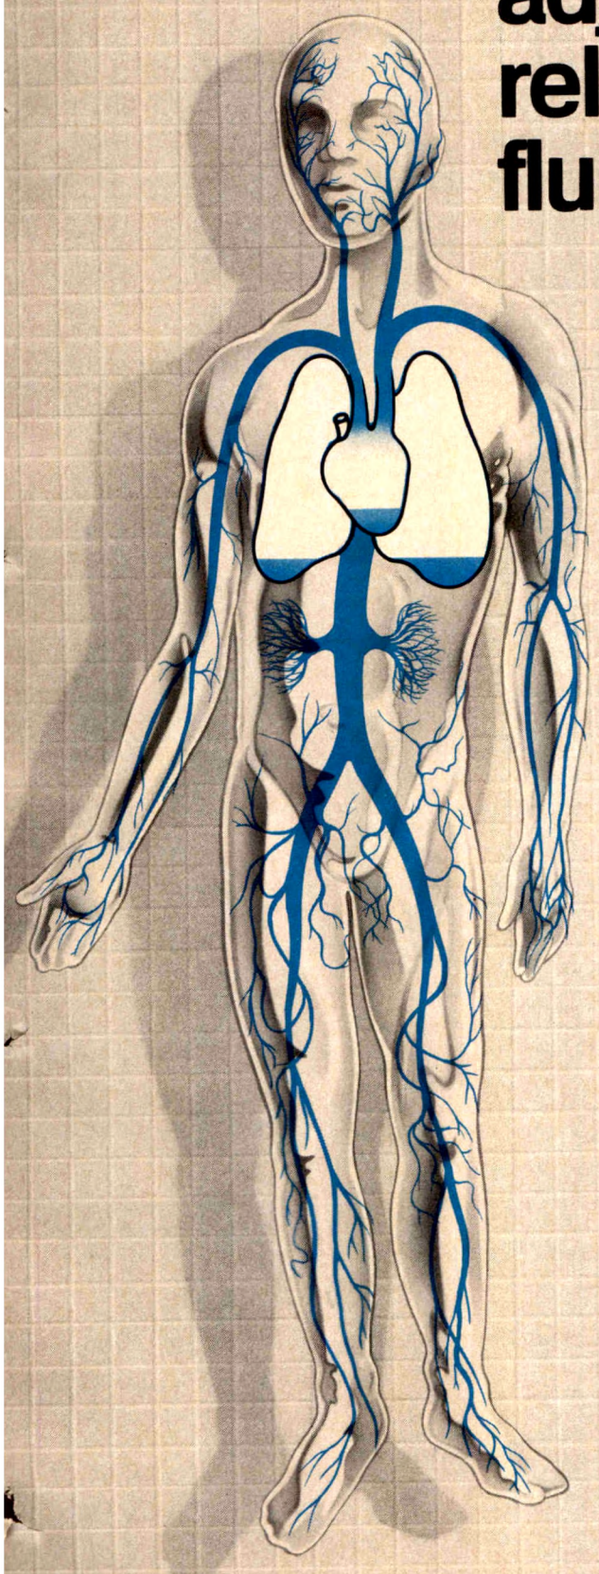
Give Tridil® (nitroglycerin) adjunctively to help relieve the fluid-burdened heart



In a dose-related manner, Tridil produces dilation of both arterial and venous beds—for a therapeutic redistribution of fluid.

Suggested therapy in early CHF

If blood pressure is normal:
Tridil to reduce preload and PCWP. Diuretics to decrease fluid volume.

If blood pressure is elevated:
Tridil should be initiated immediately to decrease preload, PCWP, and blood pressure, while maintaining coronary perfusion.

Suggested therapy in late CHF

If blood pressure is normal or only moderately depressed:
Vasopressors and Tridil adjunctively, with continuous hemodynamic monitoring.

If blood pressure is significantly depressed:
Vasopressors and Tridil adjunctively to reduce preload, afterload, and PCWP. Dopamine to increase the contractility of the myocardium. PCWP should be monitored.

Use of nonabsorbing Tridilset®

Sorptive loss of Tridil may range up to 80% when infused through a conventional PVC administration set[2] To overcome this problem, administer Tridil through Tridilset administration set or Tridilset V.I.P.™ volumetric pump connector set.

The most frequent adverse reaction in patients treated with Tridil is headache. Please see the following page for a brief summary of prescribing information. Note: Tridil is a potent drug and must be diluted before infusion.

For additional information, contact the Medical Services Department, American Critical Care, division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, IL 60085, Phone 312/473-3000.

2. Baaske DM, et al: Administration set suitable for use with intravenous nitroglycerin. *Am J Hosp Pharm* 1982;39:121-122.

TRIDIL® (nitroglycerin) SYSTEM

American Critical Care

TRIDIL® (nitroglycerin)

Brief Summary of Full Prescribing Information

NOT FOR DIRECT INTRAVENOUS INJECTION. TRIDIL® MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION (SEE DOSAGE AND ADMINISTRATION SECTION OF FULL PRESCRIBING INFORMATION). THE ADMINISTRATION SET USED FOR INFUSION WILL AFFECT THE AMOUNT OF TRIDIL DELIVERED TO THE PATIENT. (SEE WARNINGS, AND DOSAGE AND ADMINISTRATION SECTIONS.)

CAUTION

SEVERAL PREPARATIONS OF NITROGLYCERIN FOR INJECTION ARE AVAILABLE. THEY DIFFER IN CONCENTRATION AND/OR VOLUME PER VIAL. WHEN SWITCHING FROM ONE PRODUCT TO ANOTHER ATTENTION MUST BE PAID TO THE DILUTION AND DOSAGE AND ADMINISTRATION INSTRUCTIONS.

CONTRAINDICATIONS

TRIDIL should not be administered to individuals with:

1. A known hypersensitivity to nitroglycerin or a known idiosyncratic reaction to organic nitrates.
2. Hypotension or uncorrected hypovolemia, as the use of TRIDIL in such states could produce severe hypotension or shock.
3. Increased intracranial pressure (e.g., head trauma or cerebral hemorrhage).
4. Constrictive pericarditis and pericardial tamponade.

WARNINGS

1. Nitroglycerin readily migrates into many plastics. To avoid absorption of nitroglycerin into plastic parenteral solution containers, the dilution and storage of TRIDIL for intravenous infusion should be made only in *glass* parenteral solution bottles.
2. Some filters absorb nitroglycerin; they should be avoided.
3. Forty to 80% of the total amount of nitroglycerin in the final diluted solution for infusion is absorbed by the polyvinyl chloride (PVC) tubing of the intravenous administration sets currently in general use. The higher rates of absorption occur when flow rates are low, nitroglycerin concentrations are high, and the administration set is long. Although the rate of loss is highest during the early phase of infusion (when flow rates are lowest) the loss is neither constant nor self-limiting; consequently no simple calculation or correction can be performed to convert the theoretical infusion rate (based on the concentration of the infusion solution) to the actual delivery rate.

Because of this problem, American Critical Care has developed TRIDILSET,® an administration set in which loss of TRIDIL is minimal (less than 1%). TRIDILSET (or a similar administration set) is recommended for infusions of TRIDIL.

DOSING INSTRUCTIONS MUST BE FOLLOWED WITH CARE. IT SHOULD BE NOTED THAT WHEN TRIDILSET IS USED, THE CALCULATED DOSE WILL BE DELIVERED TO THE PATIENT BECAUSE THE LOSS OF TRIDIL DUE TO ABSORPTION IN STANDARD PVC TUBING WILL BE KEPT TO A MINIMUM. NOTE THAT THE DOSAGES COMMONLY USED IN PUBLISHED STUDIES UTILIZED GENERAL-USE PVC ADMINISTRATION SETS AND RECOMMENDED DOSES BASED ON THIS EXPERIENCE ARE TOO HIGH WHEN TRIDILSET IS USED.

PRECAUTIONS

TRIDIL (nitroglycerin) should be used with caution in patients with severe liver or renal disease.

Excessive hypotension, especially for prolonged periods of time, must be avoided because of possible deleterious effects on the brain, heart, liver, and kidney from poor perfusion and the attendant risk of ischemia, thrombosis, and altered function of these organs. Paradoxical bradycardia and increased angina pectoris may accompany nitroglycerin-induced hypotension. Patients with normal or low pulmonary capillary wedge pressure are especially sensitive to the hypotensive effects of TRIDIL. If pulmonary capillary wedge pressure is being monitored, it will be noted that a fall in wedge pressure precedes the onset of arterial hypotension, and the pulmonary capillary wedge pressure is thus a useful guide to safe titration of the drug.

Carcinogenesis, mutagenesis, impairment of fertility

No long-term studies in animals were performed to evaluate carcinogenic potential of TRIDIL.

Pregnancy

Category C. Animal reproduction studies have not been conducted with TRIDIL. It is also not known whether TRIDIL can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. TRIDIL should be given to a pregnant woman only if clearly needed.

Nursing Mothers

It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TRIDIL is administered to a nursing woman.

Pediatric Use

The safety and effectiveness of TRIDIL in children have not been established.

ADVERSE REACTIONS

The most frequent adverse reaction in patients treated with TRIDIL is headache, which occurs in approximately 2% of patients. Other adverse reactions occurring in less than 1% of patients are the following: tachycardia, nausea, vomiting, apprehension, restlessness, muscle twitching, retrosternal discomfort, palpitations, dizziness and abdominal pain.

The following additional adverse reactions have been reported with the oral and/or topical use of nitroglycerin: cutaneous flushing, weakness, and occasionally drug rash or exfoliative dermatitis.

OVERDOSAGE

Accidental overdosage of TRIDIL may result in severe hypotension and reflex tachycardia which can be treated by elevating the legs and decreasing or temporarily terminating the infusion until the patient's condition stabilizes. Since the duration of the hemodynamic effects following TRIDIL administration is quite short, additional corrective measures are usually not required. However, if further therapy is indicated, administration of an intravenous alpha adrenergic agonist (e.g., methoxamine or phenylephrine) should be considered.

DOSAGE AND ADMINISTRATION

(For complete information, please see Full Prescribing Information)

NOT FOR DIRECT INTRAVENOUS INJECTION

TRIDIL IS A CONCENTRATED, POTENT DRUG WHICH MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION. TRIDIL SHOULD NOT BE ADMIXED WITH OTHER DRUGS.

Some patients with normal or low left ventricular filling pressures or pulmonary capillary wedge pressure (e.g., angina patients without other complications) may be hypersensitive to the effects of TRIDIL and may respond fully to doses as small as 5 mcg/min. These patients require especially careful titration and monitoring.

There is no fixed optimum dose of TRIDIL. Due to variations in the responsiveness of individual patients to the drug, each patient must be titrated to the desired level of hemodynamic function. Therefore, continuous monitoring of physiologic parameters (e.g., blood pressure and heart rate in all patients, other measurements such as pulmonary capillary wedge pressure, as appropriate), MUST BE PERFORMED to achieve the correct dose. Adequate systemic blood pressure and coronary perfusion pressure must be maintained.

HOW SUPPLIED

NDC 0094-0090-05, 25 mg-5 ml ampul. NDC 0094-0090-10, 50 mg-10 ml ampul. Each ml contains 5 mg nitroglycerin. Protect from freezing.

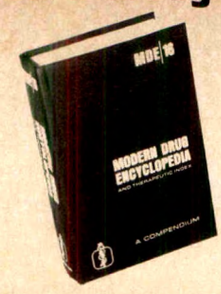
How thorough and unbiased is your drug reference?



If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Gonzales, R.Ph., B.S. Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

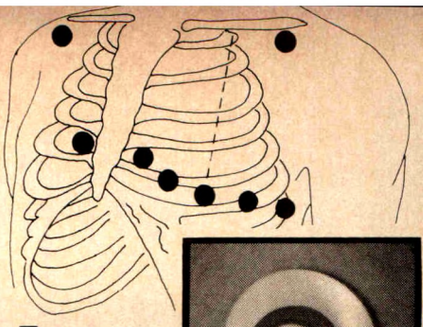
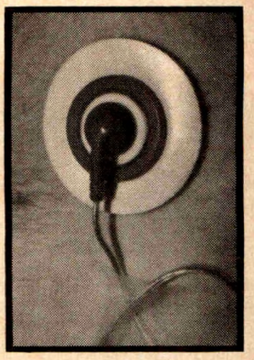
At last! A how-to book for Holter monitoring!





Ambulatory Electrocardiography: Applications and Techniques

By Susan L. Horner, B.S., M.Ed.

Holter monitoring, or ambulatory electrocardiography, depends for its validity on the ability of the EKG technician or nurse to make proper application of the equipment to the patient. While many fine books provide the physician with detailed information on the interpretation of EKG results, there has been no basic text/reference on techniques, applications, and reporting for the procedure itself.

A problem no longer. Susan L. Horner has written a technologist-level guide to the use of ambulatory EKG recording equipment, including full disclosure, that is unmatched for its clarity, brevity, and utility. As such, it will be invaluable in the training of EKG technicians and nurses. Maintaining clinical quality control and validating results rests on the trained reader. Careful observance of the procedures presented in this book will go far toward the standardization of scanning functions and report processing.

7⅜" x 9¼". About 400 Pages. 458 Illustrations. Paperback. 1983. 65-07487. $17.50

SAY HELLO TO
CINEREX™

Agfa-Gevaert Rex has changed the name of its Cine Imaging Systems Division and trademark...and here's what that change means to you:

1. It reinforces the relationship between Agfa-Gevaert Rex and our Cine Imaging Systems Division.

2. It means that the cine imaging products you have so overwhelmingly accepted will eventually all have new labels, but will be exactly the same in all other respects...the industry's best.

3. The Imaging Specialists you have been working with will continue to serve you as before, and our technical support, quality management and training programs will remain the industry's standard.

4. It means that Agfa-Gevaert, one of the world's leading manufacturers of photographic and radiographic products, will be introducing new CINEREX™ products for cardiologists and cath labs.

5. And...although you may be seeing both our old brand name and our new one on your shelves for a while, soon it will all be CINEREX.

So start thinking CINEREX...but don't be embarrassed if you forget and call us by our old name. Good things are hard to forget.

CINEREX™

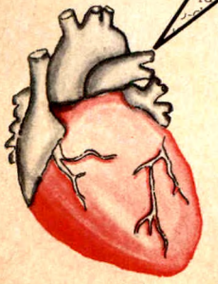
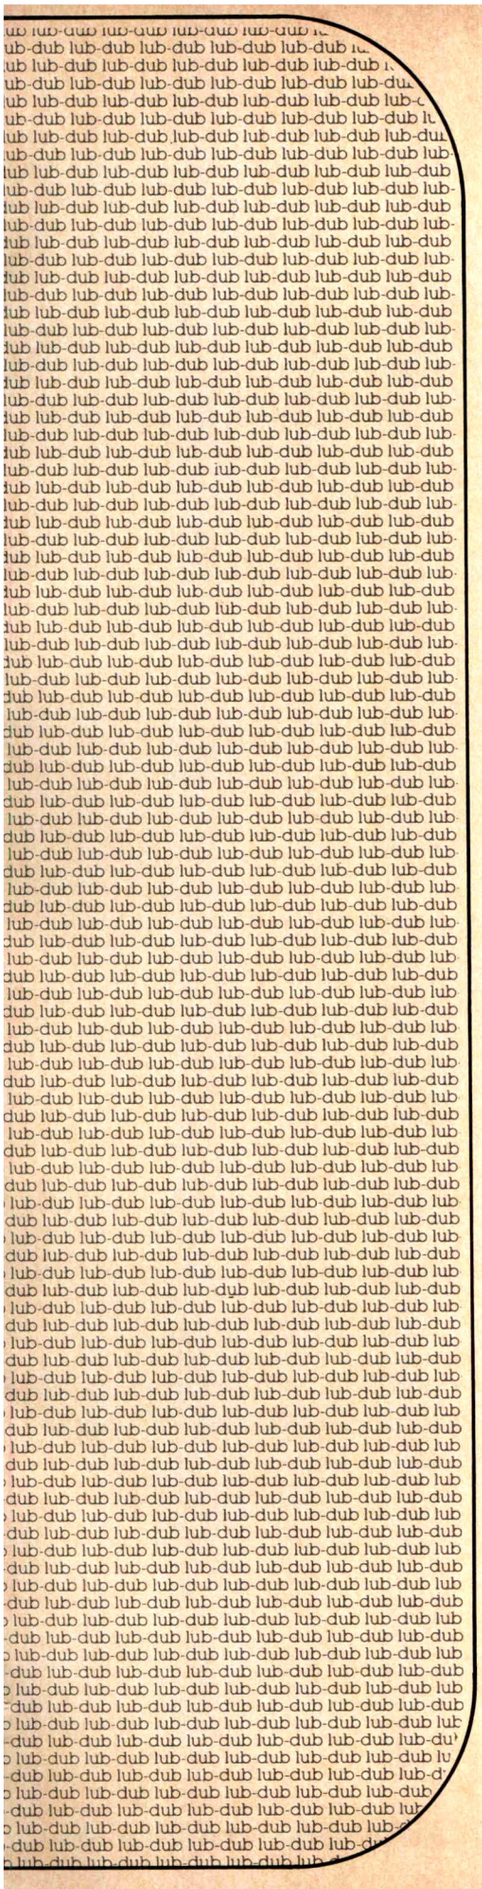
25,000,000,000
beats later
and counting





Norpace®
(disopyramide phosphate)
100-mg and 150-mg capsules

The brand that counts most often in control of dysrhythmia
Five years on the market...7 million patient-months of experience...more than 7 million prescriptions dispensed...and the beat goes on.

Norpace® CR
(disopyramide phosphate)
controlled release
100-mg and 150-mg capsules

True 12-hour dosing convenience
Now, with Norpace CR, you can add true 12-hour dosing convenience to the established efficacy of Norpace...with no increase in cost to the patient.

As a consequence of the negative inotropic properties of disopyramide phosphate, adequate cardiac function must be established and maintained. Norpace/Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac dysrhythmia.

SEARLE

Please see the next page for a brief summary of the complete prescribing information.

Norpace®
(disopyramide phosphate) 100-mg and 150-mg capsules

Norpace® CR controlled release
(disopyramide phosphate) 100-mg and 150-mg capsules

the leading branded antiarrhythmic agent

Before prescribing, please consult current complete prescribing information, a summary of which follows: **Indications:** For suppression and prevention of recurrence of the following cardiac arrhythmias: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Norpace CR should not be used initially if rapid establishment of disopyramide plasma levels is desired. Oral disopyramide phosphate has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Norpace or Norpace CR may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace or Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace or Norpace CR, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace or Norpace CR should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace or Norpace CR should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patients should be monitored closely, and discontinuation of Norpace or Norpace CR considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace or Norpace CR with other Type 1 antiarrhythmic agents and/or propranolol should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace or Norpace CR should be reduced. If the block persists, continuation of Norpace or Norpace CR must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi-, or trifascicular block requires discontinuation of drug unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, disopyramide phosphate should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken. In patients with a family history of glaucoma, intraocular pressure should be measured before initiating Norpace or Norpace CR therapy. Precautions:** Patients with atrial flutter or fibrillation should be digitalized prior to Norpace or Norpace CR administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace or Norpace CR is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of disopyramide phosphate. Therefore, a loading dose of Norpace should not be given to such patients, and initial dosage and subsequent dosage adjustments should be made under close supervision. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs for overdosage. Norpace CR is not recommended for patients with severe renal insufficiency. Concomitant administration of disopyramide phosphate with phenytoin or other hepatic enzyme inducers may cause lower disopyramide plasma levels. Antiarrhythmic drugs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced in patients with hyperkalemia. Therefore, potassium abnormalities should be corrected before starting Norpace or Norpace CR therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood. **Norpace has been reported to stimulate contractions of the pregnant uterus.** Use of Norpace or Norpace CR in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace or Norpace CR on the fetus during delivery or on the course of labor and delivery are unknown. **Adverse Reactions:** Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, 'dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported, as have fever, respiratory difficulty, thrombocytopenia, and gynecomastia. **Dosage and Administration:** Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg/day given in divided doses: q6h for Norpace and q12h for Norpace CR. **See current complete prescribing information for dosage recommendations.**

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

Hemodynamic and Myocardial Performance Characteristics After Verapamil Use in Congestive Heart Failure

JACK FERLINZ, MD and P. DENNIS CITRON, MD

Because of its intrinsic negative inotropic effect, the administration of the recently introduced calcium antagonist, verapamil, is thought to be contraindicated in presence of congestive heart failure (CHF). Yet, as CHF is frequently associated with arrhythmias and angina pectoris, and verapamil possesses potent antiarrhythmic and antianginal properties that could be of great benefit to selected patients with CHF, this study was undertaken to determine whether verapamil can be given to such subjects safely. For this purpose, 14 patients with CHF were studied in the control (preverapamil) state with a combined hemodynamic-cineangiographic approach; the same interventions were repeated during intravenous verapamil administration (0.1 mg/kg bolus, followed by 0.005 mg/kg/min infusion). Verapamil markedly lowered mean aortic pressure (95 ± 19 to 81 ± 12 mm Hg, $p < 0.001$) and systemic vascular resistance (1,953 ± 873 to 1,417 ± 454 dynes s cm^{-5}, $p < 0.01$). Simultaneously, indexes of left ventricular (LV) performance substantially improved: the ejection fraction increased from 29 ± 13 to 37 ± 17% ($p < 0.01$), and mean velocity of circumferential fiber shortening increased from 0.45 ± 0.18 to 0.64 ± 0.28 circ/s ($p < 0.001$). Cardiac index also increased (from 1.98 ± 0.49 liters/m^2/min before verapamil to 2.24 ± 0.60 liters/m^2/min after verapamil), although this improvement did not become statistically significant. No appreciable changes were noted in the heart rate, LV end-diastolic pressure, or mean pulmonary arterial or pulmonary capillary wedge pressure. Thus, the intrinsic negative inotropic activity of intravenous verapamil in therapeutic doses generally does not represent a serious drawback even in patients with CHF; its potent unloading vasodilatory properties more than compensate for any intrinsic decrease in LV contractility, and can thereby actually improve overall cardiac function.

Calcium antagonists represent one of the most promising advances in cardiovascular pharmacology within the last decade. Their clinical usefulness was initially thought to be greatly limited, however, because of the vast array of presumed contraindications for their use. It was believed, for instance, that verapamil should be used only with great caution (if at all) in patients with coronary artery disease because both verapamil[1,2] and ischemia[3,4] interfere with the movement of calcium ions to the contractile proteins of the myocardial cells, and could in theory synergistically impede calcium transport, causing a profound depression of myocardial contractility. Recent studies in our laboratory[5,6] have shown that these fears were not justified, that verapamil can actually improve left ventricular (LV) function of patients with coronary heart disease, and that this effect can be documented not only in subjects with normal LV function, but also in patients with substantial LV asynergy.[7,8] It is still maintained, however, that verapamil should not be given to patients with congestive heart failure (CHF) because, under these circumstances, the intrinsic negative inotropic effect of verapamil may not only exacerbate CHF, but could conceivably even lead to fatal complications. To the extent that arrhythmias are exceedingly common (and angina pectoris fairly frequent) in patients with CHF, and verapamil is probably the drug of choice for many, the usefulness of the drug would be severely curtailed if the presence of CHF indeed represented an absolute contraindication to its administration. This study was therefore undertaken to characterize in detail verapamil's effects

From the Cardiovascular Section, Medical Service, Veterans Administration Medical Center, Long Beach, California, and the University of California School of Medicine, Irvine, California. Presented in part at the 55th Scientific Session of the American Heart Association, Dallas Texas, November 1982. Manuscript received September 14, 1982; revised manuscript received December 21, 1982, accepted December 22, 1982.

History of CHF	All

* Mean ± 1 standard deviation.
CHF = congestive heart failure; EF = ejection fraction; LV = left ventricular; MAS = minor axis shortening.

on the cardiovascular system of patients with CHF, and to establish whether intravenous verapamil can be given to such subjects safely despite previous caveats.

Methods

Fourteen consecutive patients with clinical, roentgenographic, and hemodynamic features of CHF who needed cardiac catheterization for purely diagnostic purposes were selected for this study. A clinical profile for the entire patient population is presented in Table I. All gave informed consent and underwent routine diagnostic cardiac catheterization studies, which, in our laboratory, include complete left and right heart hemodynamic evaluation, cardiac output determination with the indocyanine green indicator-dilution technique, selective left ventriculography, and coronary arteriography. All patients were in normal sinus rhythm; none had significant valvular or congenital lesions. Patients with clinically significant renal or hepatic failure, left bundle branch block, sinus bradycardia, systolic blood pressure <90 mm Hg, or recent myocardial infarction were excluded from the study. No patient had to be excluded from the study because of adverse effects caused by verapamil, or because complete hemodynamic and volumetric evaluation could not be performed for clinical or technical reasons.

All patients were receiving other cardiovascular medications, but in each instance all drugs except sublingual nitroglycerin were discontinued at least 3 days before the study. All patients were carefully monitored throughout the drug wash-out period for any untoward effects related to the temporary cessation of their medications. Some patients had mild to moderate increases in their symptoms (mostly shortness of breath), but there was no obvious clinical evidence for further deterioration of their cardiac function which would mandate the resumption of prior medical therapy before the study could be initiated. Most subjects (13) were receiving digitalis preparations before the study; the digoxin plasma drug level was <0.50 ng/ml (the limit of our laboratory's ability to determine the presence of the drug) at the time of the study in every single case. No patient had to take nitroglycerin for at least 10 hours before cardiac catheterization.

After the first ventriculogram and coronary arteriography, 0.1 mg/kg of verapamil was given as a bolus intravenously over a 2-minute period; the intravenous verapamil infusion of 0.005 mg/kg/min was started with a Harvard infusion pump immediately after the bolus injection and continued until all data were collected. The mean bolus dose of verapamil was 7.8 ± 1.4 mg; the infusion dose 7.4 ± 3.1 mg, and the total dose 15.3 ± 4.4 mg; the length of the infusion averaged 18 ± 4 minutes. Forty-five minutes after the first ventriculography (and 15 minutes after coronary angiography), the second left ventriculogram was performed during verapamil infusion. Forty-five minutes were allowed to elapse between first and second ventriculograms to eliminate the pharmacologic effects of the contrast medium on myocardial contractility,[9] and 15 minutes elapsed after the coronary cineangiography in order to avoid the possible effects of transient reactive hyperemia on myocardial contractility.[10]

TABLE II Cardiovascular Changes Induced by Verapamil Administration

Variable	Before Verapamil (Mean ± SD)	After Verapamil (Mean ± SD)	Significance (p)

E_{cc} (diastolic)	0.70 ± 0.10	0.69 ± 0.12	NS
E_{cc} (systolic)	0.76 ± 0.08	0.76 ± 0.11	NS

AP = arterial pressure; $(A\text{-}V)O_2$ = arteriovenous difference; CI = cardiac index; Ecc = eccentricity; EF = ejection fraction; EDVI = end-diastolic volume index; ESVI = end-systolic volume index; HR = heart rate; LVEDP = left ventricular end-diastolic pressure; NS = not significant; PAP = pulmonary artery pressure; PCWP = pulmonary capillary wedge pressure; PVR = pulmonary vascular resistance; RAP = right atrial pressure; RVEDP = right ventricular end-diastolic pressure; SD = standard deviation; SVI = stroke volume index; SVR = systemic vascular resistance; V-gram = cineangiographic ventriculogram; Vcf = mean velocity of circumferential fiber shortening.

Both selective left ventriculograms were obtained with a No. 8 Cordis pigtail catheter positioned in the left ventricle. Forty-five to 50 ml of 76% meglumine sodium diatrizoate (Renografin®-76) was injected over a 3-second interval. Left ventriculograms in 30° right anterior oblique position were recorded at 64 frames/s on 35 mm Ilford Cinegram F film with a Philips 9-inch image intensifier. Two independent observers analyzed only the first 4 beats after complete opacification. If an infrequent premature ventricular contraction was detected, at least 2 successive normal sinus beats (after the premature beat) had to occur before a frame was selected for analysis.

A modification[11] of the area-length method of Dodge[12] was used in the analysis of all LV volumes. End-diastolic volume index (EDVI), end-systolic volume index (ESVI), stroke volume index (SVI), and ejection fraction (EF = SVI/EDVI) were calculated for each patient.

Each ventriculogram was interpreted qualitatively for vigor and uniformity of contractions at all points along the LV outline. A quantitative analysis was performed by combining previously described approaches[13,14] and using internal thoracic structures (spine, rib margins, or a diaphragm) as fixed references. End-systolic (ES) and end-diastolic (ED) images were fitted with a longitudinal axis (obtained by dividing the

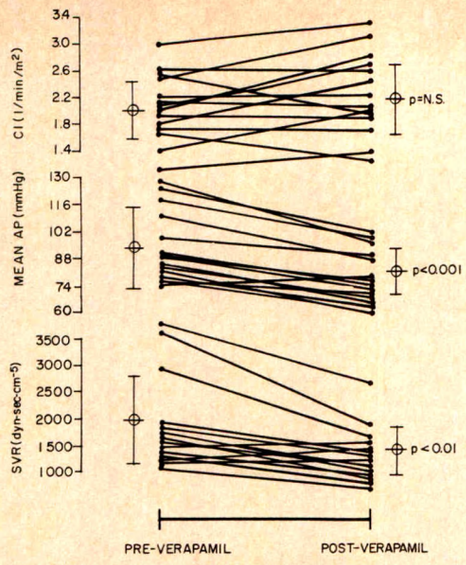

FIGURE 1. Changes in cardiac index (CI), mean arterial pressure (AP), and systemic vascular resistance (SVR) with verapamil therapy. N.S. = not significant.

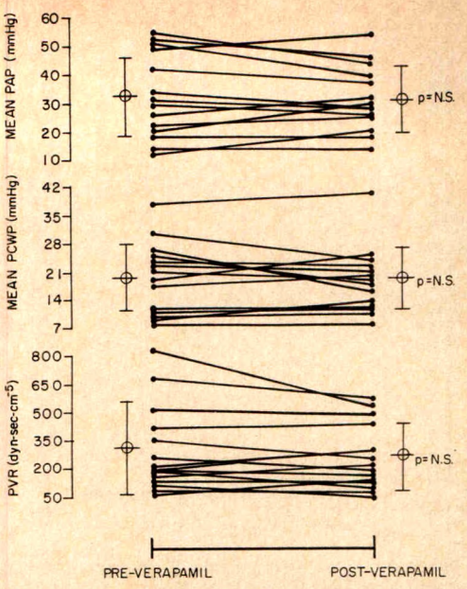

FIGURE 2. Effects of verapamil on right-sided pressures (mean pulmonary artery [PAP] and mean pulmonary capillary wedge [PCWP]) and pulmonary vascular resistance (PVR). N.S. = not significant.

images with a connecting line between the bisected aortic valve and the ventricular apex) and 6 hemiaxes (perpendicular to the longitudinal axis, which was divided into 4 equal segments). The longitudinal axis and each hemiaxis were then measured and normalized as percent decrease (or increase) in length from the ED dimension: Percent shortening = [(ED axis − ES axis)/ED axis] ×100.

A hypokinetic zone was defined when <25% hemiaxis shortening was observed in the initial ventriculogram.[15] According to the classification of Herman et al,[16] hypokinesia represented the mildest form of asynergy, followed by increasingly more pronounced LV wall-motion abnormalities when akinesia and dyskinesia were encountered. An increase in shortening ≥10% after administration of verapamil was considered an improvement in an asynergic segment,[15] and a decrease ≥10% a deterioration.

Cardiac output (CO), arterial-venous difference, and pressure data were collected just before each ventriculogram. CO was determined with the Lyons indocyanine green indicator-dilution computer by averaging 4 sequential measurements. All pressures—aortic (AP) and pulmonary artery (PAP) systolic, diastolic, and mean; right and left ventricular systolic and end-diastolic; mean right atrial (RAP); and mean pulmonary capillary wedge (PCWP)—were measured with Statham model P23Db strain gauges and recorded with an Electronics for Medicine VR-16 recorder over 3 full respiratory cycles. Systemic pressure was recorded 1, 3, 5, 10, and 15 minutes after the verapamil bolus was administered. Blood samples were drawn for serum verapamil level determination at the same time intervals, and assayed with high-pressure liquid chromatography[17] in the Bio-Science Laboratories. Heart rate was monitored throughout the study. In addition, systemic vascular resistance (SVR = [mean AP − mean RAP]/CO), pulmonary vascular resistance (PVR = [mean PAP − mean PCWP]/CO), and mean velocity of circumferential fiber shortening (Vcf = [^{d}ED − ^{d}ES]/[^{d}ED × ejection time], where ^{d}ED and ^{d}ES are left ventricular minor axes in end-diastole and end-systole),[18] were calculated for each patient.

Because it was anticipated that the LV geometry of these subjects with CHF will be substantially distorted, the LV eccentricity (E_{cc})[19] or "globularity"[20] was also determined in end-systole and end-diastole by using the expression: $E_{cc} = \sqrt{(\frac{1}{2}\,l)^2 - (\frac{1}{2}\,d)^2}/\frac{1}{2}\,l$, where l is the directly measured longitudinal axis and d the calculated minor axis (d = [4 × LV area]/[π × l]). In this schema, E_{cc} varies from 0 to 1, a perfect sphere having the E_{cc} of zero. A failed, dilated, spherical ventricle will, therefore, have a lower E_{cc} than a normal, elongated, ellipsoid one. Furthermore, the normal change in LV geometry from a more globular shape at end-diastole to a more elongated configuration at end-systole is usually attenuated in failing hearts.

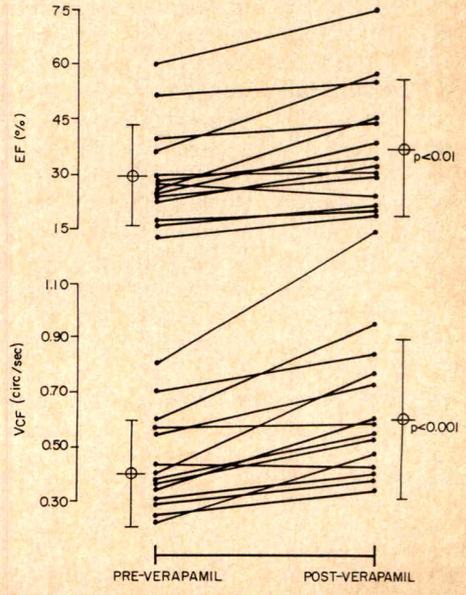

FIGURE 3. Verapamil's influence on indexes of myocardial performance (ejection fraction [EF] and mean velocity of circumferential fiber shortening [VCF]).

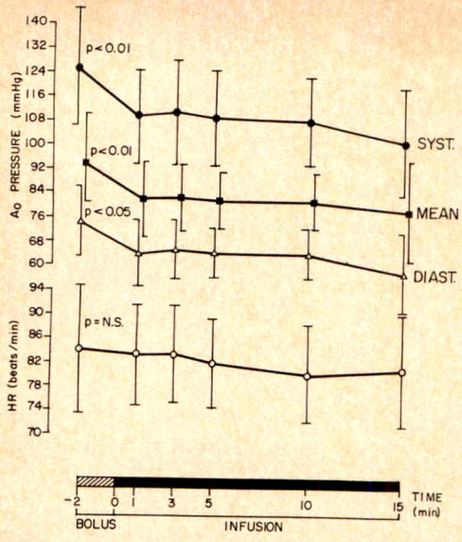

FIGURE 4. Effects of verapamil on aortic (Ao) pressures and heart rate (HR) after bolus and during infusion. (P values denote the significance of verapamil-induced changes in comparison with the control state.) DIAST. = diastolic; SYST. = systolic.

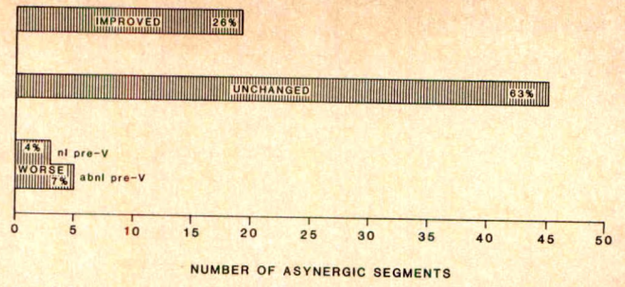

FIGURE 5. Changes in left ventricular contractility after administration of verapamil (V). abnl = abnormal; nl = normal.

All coronary cineangiograms were of high technical quality. Significant coronary artery disease was considered present only when there was at least a 75% diameter occlusion of at least 1 of the 3 coronary arteries, and when this observation was confirmed by 2 independent observers.

All data were analyzed with the 2-tailed t test for paired variables.

Results

The complete mean hemodynamic and volumetric data obtained before and after verapamil administration for the entire group are given in Table II, and a summary of key cardiovascular findings for each patient in Figures 1, 2, and 3. Verapamil markedly lowered aortic pressure and systemic vascular resistance. The decrease in systolic, mean, and diastolic aortic pressure occurred almost immediately after bolus administration, and was then effectively maintained with only very minor fluctuations at this lower level throughout the duration of the infusion (Fig. 4). While the decrease in aortic pressure from control values was highly significant, none of the minor variations that occurred after the verapamil infusion was started were statistically significant when compared with each other. Heart rate, however, remained essentially unchanged when values before and after verapamil administration were compared (Fig. 4). Specifically, heart rates recorded during CO measurements and ventricular cineangiography were virtually identical before and after administration of verapamil and could not, therefore, influence the observed results.

Verapamil caused a significant increase in the right atrial and right ventricular end-diastolic pressure, but there was actually a slight decrease in the mean PAP, PCWP, and PVR, and the LV end-diastolic pressure (LVEDP). Arterial-venous difference [(A-V)O_2] and CO were both substantially improved, achieving a statistical significance for the former but not for the latter. Volumetric analysis revealed that LV end-diastolic volume does not change after verapamil administration. End-systolic volume decreases, however, causing a significant increase in stroke volume, ejection fraction, and velocity of circumferential fiber shortening (Vcf).

Verapamil did not cause a further distortion of LV geometry in that LV E_{cc} did not change during verapamil infusion. Furthermore, while all patients had regional disorders of LV contractility (delineated by abnormal shortening of 72 hemiaxes) after administration of verapamil, 19 of 72 asynergic segments improved (26%), 45 remained unchanged (63%), and 5 worsened (7%). In addition, 3 previously normal segments (4%) became asynergic after verapamil. Overall, however, 89% of all asynergic (or potentially asynergic) segments improved or remained the same after the drug was administered, while only 11% deteriorated further (Fig. 5).

Serum verapamil level assay became available to us when the last patient was enrolled in the study. Figure 6 depicts the blood levels obtained in this subject during the bolus and the infusion parts of the experiment. Very high initial serum verapamil levels were registered after the bolus administration; the blood levels then stabilized between 100 and 200 ng/ml during verapamil infusion. (In a recent study investigating the effects of intravenous verapamil on the hemodynamic status of patients with coronary artery disease, similar blood levels have been shown to produce a substantial circulatory response.[21]) Concomitantly with the increase in the serum verapamil concentration, a large decrease in the mean aortic pressure and a moderate decrease in the heart rate were also observed (Fig. 6). Hemodynamic and volumetric variables collected in the same patient after a steady-state serum verapamil concentration was reached are depicted in Figure 7. A beneficial response in all measured variables with verapamil is unmistakable.

Discussion

The earlier concepts which have maintained that administration of verapamil produces profound negative inotropic effects even in normal hearts[22–24] have been largely abandoned in view of the extensive recent evidence demonstrating that verapamil acts more as an

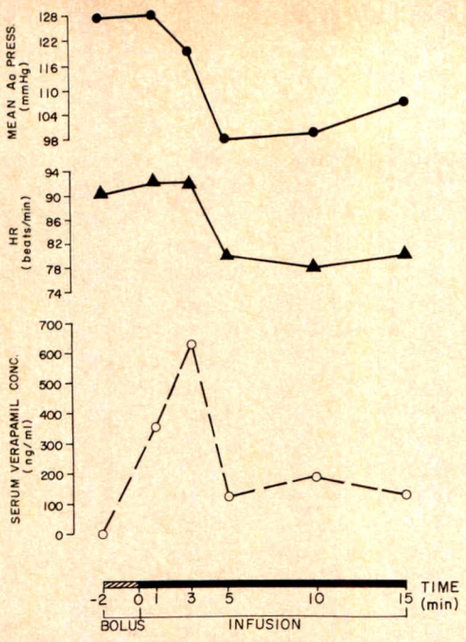

FIGURE 6. Serum verapamil blood levels and concomitant changes in mean aortic (Ao) pressure and heart rate (HR) after bolus and during infusion. CONC. = concentration; PRESS. = pressure.

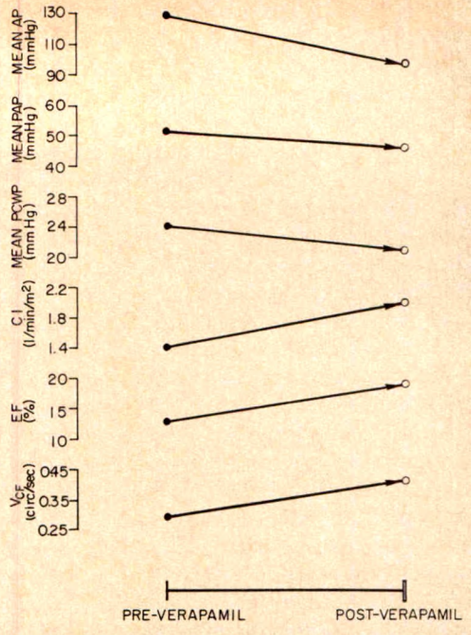

FIGURE 7. Beneficial response in all measured variables (mean arterial pressure [AP], mean pulmonary artery pressure [PAP], mean pulmonary capillary wedge pressure [PCWP], cardiac index [CI], ejection fraction [EF], and mean velocity of circumferential fiber shortening [V_{cf}]) of the patient whose verapamil blood levels are depicted in Figure 6.

unloading agent than a myocardial depressant.[5,6,25–28] It is still widely believed, however, that verapamil should be given with the greatest caution (if at all) to patients who have a significant impairment of LV function, and that subjects with severe CHF should be excluded altogether.[29–31] Yet, because patients with CHF routinely have concomitant cardiac conditions (such as arrhythmias and angina) that are ideally suited for verapamil therapy, a very large number of candidates for verapamil treatment are denied the benefit of this drug because of such caveats.

Preliminary reports have already indicated that some investigators do not find CHF an absolute contraindication to verapamil use,[8,32,33] especially when CHF occurs in the setting of supraventricular tachycardia.[32,33] It remains to be seen, however, what actual hemodynamic changes take place when intravenous verapamil is administered to patients with *severe* CHF who are in normal sinus rhythm, and the extent (if any) of subsequent LV deterioration.

Previous experiments with a different calcium antagonist which does not possess antiarrhythmic properties—nifedipine—have demonstrated that this drug can not only be given safely to patients with CHF,[34–38] but that it can actually be used to treat pulmonary edema.[39] This approach was purportedly not to be used with verapamil, however, because verapamil was not the vasodilator of nearly the same potency as nifedipine,[29,40–42] and its negative inotropic effects would exert themselves at a substantially lower unloading plateau than nifedipine's.[43–45]

These premises were not substantiated in our study. Ejection fraction and Vcf increased in all but 1 patient with verapamil treatment, and even in this subject the decrease was only slight. Furthermore, LV E_{cc}, while obviously already abnormal in the control phase of the study, did not worsen during verapamil administration. (Normal LV E_{cc} varies from 0.85 ± 0.01 in end-diastole to 0.92 ± 0.01 in end-systole; in severely decompensated hearts LV E_{cc} decreases to 0.70 ± 0.01 in end-diastole and 0.73 ± 0.01 in end-systole.[20]) Finally, we found no evidence that verapamil will exacerbate LV asynergy in patients with CHF, since 89% of all asynergic segments improved or remained the same after the drug was administered, and only 11% deteriorated further. In 2 patients spontaneous pulmonary edema developed in the cardiac catheterization laboratory during the control phase of the study, before any amount of verapamil was administered. Verapamil was then given to them in the quantities mandated by the protocol not only because it was considered safe to complete the experiment, but also to ascertain whether pulmonary edema can be ameliorated by verapamil. Both patients' conditions improved.

It is apparent that the major beneficial attribute of verapamil promulgating the improvement in the LV function of our CHF patients is its ability to induce potent peripheral vasodilatation. Verapamil produced a highly significant drop in the aortic pressure and systemic vascular resistance, thereby greatly reducing the impedance to ventricular ejection. Additional beneficial effect may be due to the drug's propensity to improve the myocardial diastolic relaxation that is often severely impaired in compromised hearts.[46–48] It is rather doubtful, however, that verapamil's potent in vitro coronary vasodilating action could exert itself in

actual patients and therefore contribute to the improvement in ventricular function through the augmented myocardial blood supply: experiments in our laboratory have shown that verapamil administration (by decreasing myocardial metabolic demands) may actually decrease the coronary flow when given to the subjects with ischemic heart disease.[49–52]

It has been well established that verapamil tends to increase right-sided pressures, PCWP, and LVEDP of patients with essentially normal hearts.[5–8,53,54] Of interest, therefore, is the finding that the patients in this study did not have increases in PAP, PCWP, or LVEDP. It is tempting to speculate that if, indeed, the normal effect of verapamil in the non-CHF patients is to augment the right heart and LV filling pressures, the potent vasodilatory properties of the drug would actually decrease these pressures in the CHF subjects (as other vasodilators commonly do) if it were not for verapamil's propensity to act otherwise. It is, therefore, possible that verapamil's failure to actually decrease the LV filling pressure in the CHF patients represents the net result of these 2 opposing modalities of action.

A number of vasodilators have been used with a fair amount of success in the treatment of CHF.[55–58] Yet, recent evidence indicates that vasodilator therapy for CHF can sometimes produce profound adverse effects.[59,60] Specifically, administration of hydralazine[61] or nifedipine[62] can trigger increased frequency of anginal attacks; with hydralazine these ischemic events sometimes lead to myocardial infarction or even death.[61] To the extent that 12 of 14 CHF patients (86%) in our study also had concomitant coronary artery disease, it was important to assess verapamil's potential to provoke similar ischemic episodes. They were not detected in any of the subjects.

Despite the encouraging nature of data presented in this study, however, it should not be assumed that verapamil is incapable of producing serious adverse effects. In this context, under no circumstances should this communication be interpreted as endorsing intravenous verapamil for the treatment of congestive heart failure, or even pulmonary edema. As already stated, 1 of our patients experienced a slight decrease in ejection fraction and Vcf; his PCWP and LVEDP concomitantly increased—albeit only a little, and his cardiac output and E_{cc} registered a modest decrease. It is conceivable that this subject came close to a total cardiovascular decompensation, and that this putative decompensation would have been mostly verapamil-related. Nevertheless, in the doses administered in this study, verapamil did not produce any overt untoward effects, and was most often hemodynamically outright beneficial.

That the dose employed is of critical importance deserves a special emphasis. Chew et al[30] have reported that a subset of 3 patients with markedly reduced LV ejection fraction and elevated mean PCWP, mean arterial pressure decreased substantially with a concomitant decrease in stroke volume index and an abrupt further increase in mean PCWP after verapamil administration. The bolus dose of verapamil used (0.145 mg/kg), however, was subtantially higher than in our study. Verapamil's negative inotropic effect becomes even more prominent at very high doses, and it eventually leads to a profound depression of myocardial contractility when such quantities of the drug are employed.[63] In the precariously functioning hearts of patients with CHF, the beneficial unloading effects of verapamil will probably be overcome fairly readily by the drug's negative inotropic effect if very large quantities of this drug are given.

This dose-dependent relation will become especially important if *oral* verapamil is to be given to patients in CHF. Epstein and Rosing[64] report serious hemodynamic complications and even deaths with use of oral verapamil in treatment of patients with hypertrophic cardiomyopathy. One of their patients with serious complications (hypotension, pulmonary edema) had an excessively high blood level of the drug. Such an overshoot can probably occur fairly readily because of the enormous interpatient variations in their first-pass metabolism of oral verapamil. In a recent study with the oral preparation, patients received a maintenance dose of 480 mg of verapamil per day, and then challenged with an additional 160 mg test dose.[65] A *25-fold* difference between patients taking this dosage was found for verapamil plasma concentrations before the test dose and a 13-fold difference after it. The concentration of the main active verapamil metabolite, norverapamil, showed a strong positive correlation with the corresponding verapamil concentrations. The problems with the unpredictable bioavailability of oral verapamil (at least as assessed by verapamil plasma concentration) are further compounded by the drug's long-term effect on the reflex adrenergic response. It has been reported that catecholamine levels are elevated when verapamil is given on a short-term basis, suggesting a decrease in peripheral resistance and reflexly increased sympathetic activity.[66] In a long run, however, these reflex-mediated responses dissipate, and CHF may develop or worsen when catecholamine levels return to control levels.

The findings from this short-term intravenous study must, therefore, not be extrapolated to the long-term action of oral verapamil in CHF. A need for a long-term evaluation of the oral preparation of this drug in CHF is pressing, and we have therefore started the consenting patients from this study on a verapamil maintenance therapy in an attempt to also elucidate its long-range cardiovascular effects.

Acknowledgment: We thank Wilma Mottin and Ruby Stubbs for their secretarial help and Gaela Palmer for her technical assistance. Verapamil was supplied by the Knoll Pharmaceutical Company, Whippany, New Jersey.

Efficacy of Prazosin in the Management of Chronic Congestive Heart Failure: A 6-Month Randomized, Double-Blind, Placebo-Controlled Study

ROY V. MARKHAM, Jr., MD, JAMES R. CORBETT, MD, ALYCE GILMORE, RN, WILLIAM A. PETTINGER, MD, and BRIAN G. FIRTH, MD, DPhil

The beneficial effects of acute prazosin therapy in patients with congestive heart failure (CHF) have been well documented; however, its chronic efficacy over several months has not previously been evaluated in a placebo-controlled manner. Therefore, an assessment was made by radionuclide ventriculography of the effect of prazosin, 20 mg/day, on left ventricular ejection fraction and end-systolic and end-diastolic volumes at rest and on peak upright bicycle exercise, as well as its effect on right ventricular ejection fraction at rest, exercise time and work load, and standard clinical variables in 23 patients with stable class III symptoms of CHF. The study consisted of a 6-month randomized, double-blind, controlled evaluation of prazosin versus placebo in patients receiving a stable dose of digitalis and diuretics for at least 1 month. At entry, the prazosin and placebo groups did not differ in any respect. Prazosin caused no demonstrable effect on clinical variables such as status of symptoms, heart rate, mean arterial pressure, and cardiothoracic ratio when compared with placebo. Prazosin also caused no demonstrable effect compared with placebo on absolute or percent changes in radionuclide variables at rest or on peak exercise, or on exercise time or exercise work load. In addition, prazosin had no consistent effect compared with placebo on plasma renin activity or plasma catecholamine levels. However, there was a slight but significant increase in weight ($p < 0.0001$) and in plasma renin activity in the upright position ($p < 0.002$) with time, as well as a tendency for the diuretic dose to increase with time in both groups. Thus, long-term prazosin therapy generally produces no demonstrable subjective or objective improvement in patients with stable, chronic class III CHF receiving digitalis and diuretic therapy.

Vasodilator therapy of congestive heart failure (CHF) represents an attractive conceptual alternative or adjunct to inotropic support of the failing heart. Prazosin, an orally active postsynaptic alpha-adrenergic antagonist,[1] has been shown to produce a balanced effect on both the venous and arterial systems, with a resultant increase in cardiac output and decrease in pulmonary congestion, in short-term studies in patients with CHF.[2–4] However, its long-term efficacy is in dispute. Tolerance appears to be a common problem,[5–9] and may be related to an increase in plasma norepinephrine levels[10,11] or plasma renin activity.[12,13] In order to further elucidate this problem, we performed a 6-month, randomized, double-blind, placebo-controlled study of the effects of prazosin in patients with New York Heart Association (NYHA) class III CHF. We assessed exercise capacity, left ventricular function at rest and during peak exercise, right ventricular function at rest, plasma renin and catecholamine levels, and standard clinical variables at several discrete points in time during the study.

Methods

Patients: The study population comprised 25 patients (14 men and 11 women, aged 30 to 76 years) with chronic CHF. Thirteen (8 men and 5 women) were randomized to prazosin and 12 (6 men and 6 women) to placebo groups. All had pre-

died suddenly. Other than hypotension in 1 patient, prazosin was tolerated well by all patients.

Clinical variables: There was no significant improvement in NYHA class attributable to prazosin at any time period (Fig. 1). There was an increase in body weight with time ($p < 0.0001$) in both groups of patients (prazosin group: at baseline 72 ± 17 kg, at 26 weeks 74 ± 18 kg; placebo group: at baseline 74 ± 17 kg, at 26 weeks 78 ± 15 kg) (Fig. 1). The difference between the groups was not significant. There was also an increase in furosemide dosage with time in both groups that did not attain the designated level of statistical significance (Fig. 1). Mean arterial pressure and heart rate, both sitting and standing, were not different at any time between the groups and did not change significantly with time. (Only the standing mean arterial pressure data are presented in Figure 1). Cardiothoracic ratio also showed no significant change with time or in response to prazosin therapy at any time period (prazosin group: at baseline 56 ± 8%, at 12 weeks 53 ± 10%, at 26 weeks 55 ± 10%; placebo group: at baseline 56 ± 7%, at 12 weeks 56 ± 8%, at 26 weeks 53 ± 9%).

Radionuclide variables: Prazosin did not produce an improvement compared with placebo in any of the radionuclide variables (Tables II and III). At rest, the left ventricular ejection fraction increased slightly, but not significantly, with time in both groups (prazosin group: 0.25 ± 0.09 at baseline, 0.27 ± 0.09 at 4 weeks, 0.30 ± 0.08 at 26 weeks; placebo group: 0.21 ± 0.08 at baseline, 0.23 ± 0.08 at 4 weeks, 0.25 ± 0.13 at 26 weeks). At peak exercise, left ventricular ejection fraction increased with time in both groups ($p < 0.004$). The difference between the groups was not significant at any time period (prazosin group: 0.24 ± 0.05 at baseline, 0.30 ± 0.08 at 4 weeks, 0.31 ± 0.10 at 26 weeks; placebo group: 0.24 ± 0.10 at baseline, 0.25 ± 0.10 at 4 weeks, 0.28 ± 0.12 at 26 weeks). There was also no clearly discernible improvement in individual patients in either of these variables in response to prazosin therapy (Figs. 2 and 3). At rest, end-diastolic and end-systolic volume indexes in the prazosin group were 151 ± 70 and 113 ± 52 ml/m^2, respectively, at baseline and did not change significantly with time. Similarly, end-diastolic and end-systolic volume indexes at baseline in the placebo group were 155 ± 62 and 125 ± 57 ml/m^2 and did not change significantly with time. At peak exercise, end-diastolic and end-systolic volume indexes also did not change significantly with time or with prazosin therapy. The right ventricular ejection fraction at baseline averaged 0.42 ± 0.19 in the prazosin group and 0.41 ± 0.18 in the placebo group and showed no significant change with time or in response to prazosin therapy. Neither the absolute nor the percent change in any of these radionuclide variables suggested a beneficial effect from prazosin therapy at any time period.

TABLE II Radionuclide and Exercise Variables (Prazosin Group)

Abbreviations as in Table I.
Twelve patients at 4 weeks, 11 patients at 12 weeks, 8 patients at 26 weeks. For RVEF, 9 patients at 4 weeks, 5 patients at 26 weeks.

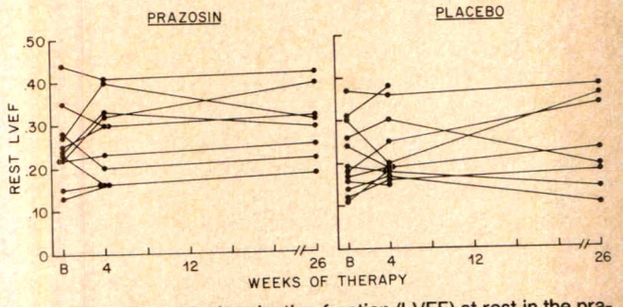

FIGURE 2. Left ventricular ejection fraction (LVEF) at rest in the prazosin- and placebo-treated patients. Each line represents the data from 1 patient. There was no significant difference in response between the 2 groups.

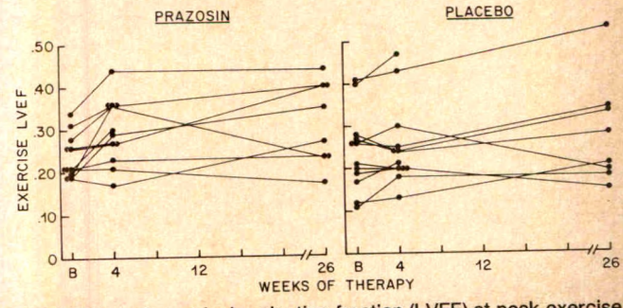

FIGURE 3. Left ventricular ejection fraction (LVEF) at peak exercise in the prazosin- and placebo-treated patients. Each line represents the data from 1 patient. There was no significant difference in response between the 2 groups.

Exercise variables: There was no significant increase with time in either total exercise duration (Fig. 4) or work load achieved (Tables I to III) in response to prazosin or placebo. Neither the absolute change nor the percent change in either of these exercise variables suggested an improvement in function in response to prazosin therapy at any time period.

Neurohumoral variables: The neurohumoral variables for each group at each time period are shown in Table IV. In the prazosin group, plasma norepinephrine levels increased in 8 of the 11 patients at 4 weeks and the mean value increased from 790 ± 280 pg/ml at baseline to 1,413 ± 1,030 pg/ml. However, this change was not significant, and at 26 weeks the plasma norepinephrine level at rest was 875 ± 638 pg/ml. Plasma norepinephrine levels at peak exercise tended to increase with time in both prazosin and placebo groups; however, this change again did not attain statistical significance. Plasma epinephrine levels showed no significant alterations with time or in response to prazosin therapy. Plasma renin activity also did not change significantly in response to prazosin therapy but increased with time, both in the standing ($p < 0.002$) and supine ($p = 0.015$) positions, in both groups.

Discussion

The beneficial effects of acute prazosin therapy in patients with CHF have been well documented.[2–4] Recently, 2 double-blind, randomized, placebo-controlled studies[12,24] demonstrated a beneficial effect from long-term prazosin therapy after 6 and 8 weeks, respectively, while a third double-blind, randomized, placebo-controlled, crossover study[25] demonstrated acute improvement in hemodynamic characteristics but marked attenuation of the hemodynamic effects after 4 weeks of prazosin therapy. The present study, which is the first double-blind, randomized, placebo-controlled study of chronic prazosin therapy in CHF that extends over several months with serial evaluations at several discrete points in time during the study demonstrated no beneficial effect at any time during this study, either at rest or during exercise.

Clinical variables: The patients randomized to prazosin and placebo were well matched in every respect (Table I). The average compliance (89% by pill count) over the total duration of the study was good. Prazosin had no demonstrable effect compared with placebo on clinical symptoms or signs at any time during the study. A consistent effect on heart rate or blood pressure, either sitting or standing, could not be demonstrated. There was also no significant change in cardiothoracic ratio as assessed by chest roentgenography at 3 or 6 months of therapy. There was a slight but significant ($p < 0.001$) increase in weight in both prazosin- and placebo-treated groups of patients with time despite a trend towards a concomitant increase in furosemide dosage. The increase in weight and furosemide dosage between the prazosin and placebo groups was not significantly different at any time. Prazosin was generally well tolerated. Only 1 patient had limiting postural hypotension and was excluded from the study after the first day of therapy.

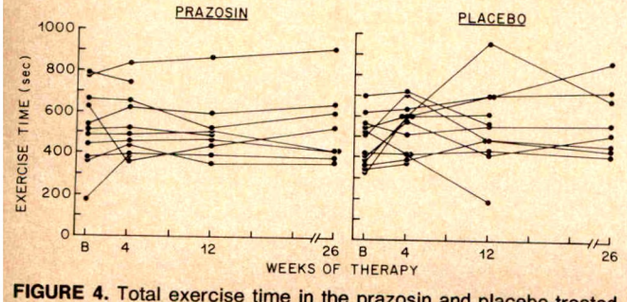

FIGURE 4. Total exercise time in the prazosin and placebo-treated patients. Each line represents the data from 1 patient. There was no significant difference in response between the 2 groups.

Radionuclide variables: Radionuclide-determined left ventricular ejection fraction, end-diastolic and end-systolic volume indexes, and right ventricular ejection fraction at rest showed no significant change in response to prazosin, either at 1 or 6 months. These findings contrast strikingly with those reported by Colucci et al who observed an increase in both left[12] and right[26] ventricular ejection fractions after 2 months of prazosin therapy. The left ventricular ejection fraction before therapy in the patients who received prazosin (0.25 ± 0.09) was similar to that reported in the study by Colucci et al[12] (0.25 ± 0.02), while the right ventricular ejection fraction was higher in our patients (0.42 ± 0.19 versus 0.28 ± 0.04). The other 2 double-blind studies of chronic prazosin therapy[24,25] did not report left ventricular ejection fractions or volumes and, therefore, cannot be compared directly with ours.

Several other investigators[27–29] have been unable to demonstrate an improvement in hemodynamic variables at rest after prazosin therapy and have suggested that the beneficial effects of prazosin in patients with CHF may only be evident during exercise. In the present study, prazosin caused no demonstrable improvement in left ventricular ejection fraction or volumes at peak exercise when compared with placebo after 1 or 6 months of therapy.

Exercise variables: Neither exercise work load nor exercise duration improved after prazosin therapy in the present study at 1, 3, or 6 months. These observations are in agreement with those reported by Harper et al[25] after 4 weeks of double-blind prazosin therapy, but differ from those reported by Colucci et al[12] and Aronow et al.[24] It is of interest that total exercise duration actually tended to increase in the placebo-treated group rather than the prazosin-treated group of patients in the present study, although this difference was not significant. This observation suggests that our inability to demonstrate a beneficial effect from prazosin on total exercise duration does not represent a type II statistical error.

Neurohumoral variables: Plasma norepinephrine levels, which provide an index of the activity of the sympathetic nervous system,[30] are generally markedly elevated in patients with CHF.[31] Since a pure alpha-adrenergic antagonist such as prazosin has no intrinsic vasodilating actions, it has been suggested that its efficacy may depend on the degree of sympathetic tone, that is, that patients with severe CHF and markedly

elevated sympathetic tone may be more responsive than those with mild CHF, who generally have less sympathetic tone.[32] In this regard it is worth noting that the levels of plasma norepinephrine at rest in the prazosin-treated patients (790 ± 280 pg/ml, range 489 to 1,389) (Table IV) are similar to those reported by Levine et al[31] and considerably higher than those reported by Colucci et al.[32] Thus, the patients in the present study are precisely those in whom one might have anticipated a beneficial response from prazosin. An increase in plasma norepinephrine levels, both at rest and during exercise, has been reported with chronic prazosin therapy.[10,11,13,32] Indeed, an increase in vascular tone resulting from this increase in plasma norepinephrine level is one of the mechanisms that has been suggested to explain the development of tolerance to prazosin. Although plasma norepinephrine levels were higher after 4 weeks of therapy than at baseline in the prazosin-treated group in the present study, this difference was not significant (Table IV). After 26 weeks of therapy, plasma norepinephrine levels at rest were similar to those at baseline. Prazosin also caused no significant increase in plasma norepinephrine at peak exercise. Plasma epinephrine levels in the present study are also similar to those reported by Levine et al[31] and did not change significantly in response to prazosin, either at rest or during peak exercise. Both plasma norepinephrine and epinephrine levels increased in response to exercise to levels similar to those reported by Francis et al.[33]

The levels of plasma renin activity at rest in the present study are similar to those reported by Dzau et al[34] in patients with well-compensated CHF. Prazosin caused no demonstrable increase in plasma renin activity when compared with placebo. However, in both groups of patients plasma renin activity increased slightly but significantly with time. Body weight also increased with time in both groups of patients. These findings may therefore be interrelated.

Limitations and implications of the study: This study is the first double-blind, randomized, placebo-controlled study of the effects of prazosin in patients with CHF, both at rest and during exercise, in a well-matched, compliant group of patients extending over several months. However, it has certain limitations. First, the effect of prazosin was assessed using noninvasive rather than invasive techniques. We[19] and other workers[35] have previously demonstrated that noninvasive techniques, such as radionuclide ventriculography, are less sensitive than invasive techniques for assessing the hemodynamic changes produced by a vasodilator agent in a patient with CHF and a dilated left ventricle. However, while we[19] were able to demonstrate a significant reduction in end-diastolic and end-systolic volumes ($p < 0.001$) and an increase in left ventricular ejection fraction ($p < 0.005$) in response to nitroprusside, no such response could be demonstrated with prazosin despite meticulous care to ensure consistent background subtraction and definition of the region of interest. It is therefore possible that more subtle hemodynamic changes due to prazosin might have been detected with invasive techniques. However, if such hemodynamic changes occurred, they did not result in any improvement in symptoms. Second, treadmill exercise testing using a modified Naughton protocol with direct measurement of oxygen consumption[36] may be a more sensitive method of assessing changes in exercise capacity than bicycle ergometry in patients with CHF. This was not done in the present study since it would have precluded simultaneous radionuclide ventriculography during exercise. Validation of the achievement of maximum exercise by metabolic measurements, a more objective endpoint than fatigue, was therefore not possible. Third, the optimal daily dosage of prazosin is in dispute. Our daily dosage of 20 mg/day is similar to that used by Colucci et al,[12] higher than that used by some,[24,25] and lower than that used by other investigators.[9] Thus, it is possible that different results might have been obtained with either a higher or lower dosage. Finally, the designated level of statistical significance merits comment. Since multiple comparisons were performed on a large number of variables, a p value of 0.05 is not sufficiently stringent. We, therefore, arbitrarily set a p value of 0.01 as significant. In a recent comparable study[37] in which fewer variables were compared, other investigators set the level of significance at $p < 0.005$ (0.05 divided by the number of variables) based on the Bonferroni adjust-

TABLE IV Neurohumoral Variables

	B	Day 2	4 Weeks	12 Weeks	26 Weeks

ment. However, even when the level of significance is set at the 0.05 level, there is no objective evidence of improvement in response to prazosin therapy at any point in time in our group of patients. These observations suggest that prazosin is not generally useful in the long-term management of a group of patients with CHF.

Acknowledgment: We acknowledge the skilled technical assistance of R. Scott Lyons, Norman Vance, Tom Rhodes, and Kay Lancaster as well as the secretarial help of Juanita Alexander. We also thank Nancy Wilson for performing the statistical analysis and James T. Willerson, MD, and C. Gunnar Blomqvist, MD, for critical comments on this manuscript.

New Insights

Toshiba SSH-40A Ultrasound Scanner
The Complete Cardiac Lab.

How do you measure commitment? With words? Toshiba prefers to have the products make the point. Newest proof: the Toshiba SSH-40A Cardiac Ultrasound Laboratory, a vivid example of our commitment to echocardiographic diagnostics.

Clinical versatility is the watchword for the SSH-40A. It means independent or simultaneous display of 2-D echocardiograms, M-Mode and Doppler images for faster, more complete diagnosis. It means you can scan with various probes for the best image quality in all patient sizes and specialized procedures. Perform two dimensional, multi-gate array Doppler flow studies and perform all cardiac function computations instantly.

Image quality? Startling. Low level echoes contain the most significant diagnostic information. The SSH-40A captures and displays them with a unique, low-noise digital system: dual microprocessors and more memory than any ultrasound instrument. Plus the powerful Digital Scan Processor provides optimum control over image quality.

Such insights, frankly, defy words. That's why we're eager to provide you with a demonstration of the SSH-40A's powerful capabilities. Then you can complete the picture yourself.

Please see the reverse side for further information.

New Insights

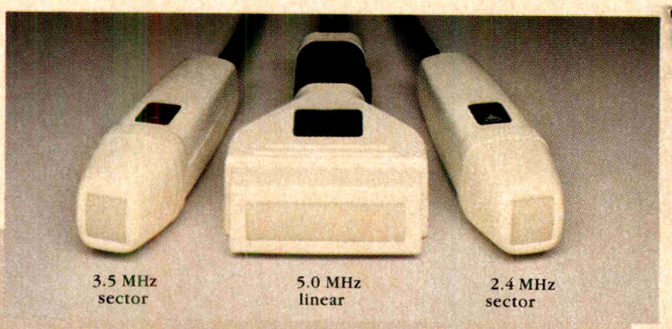
TOSHIBA SSH-40A CARDIAC ULTRASOUND LABORATORY.

The Toshiba SSH-40A is a complete cardiac ultrasound laboratory that combines clinical versatility, superior image quality and powerful digital scan processing to provide a host of features for new insights into cardiac diagnoses.

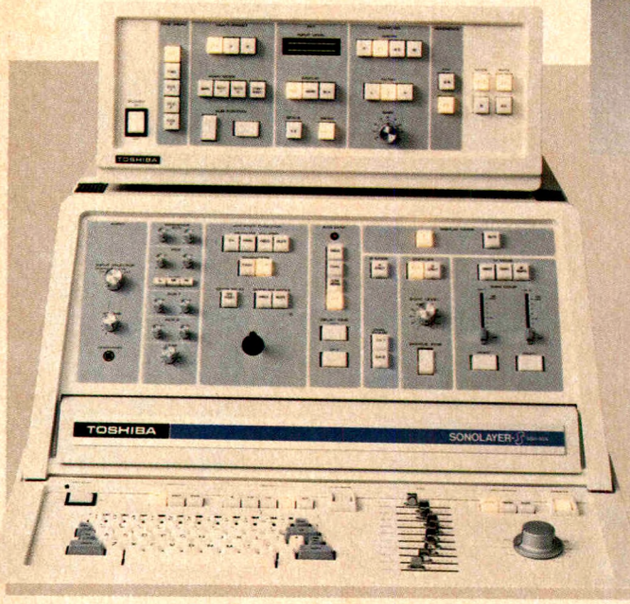
The SSH-40A is available with a standard 3.5 MHz probe and optional 5 MHz linear scan probe and 2.4 MHz sector scan probe to enable accurate examinations of all patients, from neonates to adults. All pertinent image and exam data, including results from computations, can be displayed. And the unique two dimensional multigate array Doppler capability enables the operator to perform flow studies, to display frequency spectrum from the digital FFT analyzer and to compute flow rate, velocity and other cardiac function data. Extensive computational algorithms are on-line to ensure fast, accurate analyses.

Superb image quality results from the advanced scanning technology incorporated in the SSH-40A. A new receiver design and a new digital scan processor provide optimized image quality with clearly defined edge differentiation and excellent tissue differentiations. A faithful display of low level echoes provides excellent gray scale resolution.

The SSH-40A delivers the image processing functions cardiologists require. Echo enhancement, post processing and other echo processing operations, synchronous freezing of two phases of a cardiac cycle, slow motion display and measurement of distances and areas on frozen images are all well within the range of this remarkable system's capabilities.



3.5 MHz sector | 5.0 MHz linear | 2.4 MHz sector



- Simultaneous 2-D imaging and dual M-Mode or Doppler operation ensures more exact correlation, faster diagnosis and state-of-the-art performance.
- Cardiac function (SV, EF, FS, CO and others), area, circumference, slope and distance can be computed at the touch of a keyboard, thanks to a selection of stored algorithms.
- Simultaneous display of two images, strobed from two selected points on the ECG cycle, allows detection of abnormal wall motion.
- Comprehensive exam data display permits date, time, frequency and patient data and image annotation to be included for more complete patient records.

For further information on the SSH-40A electronic sector scanner, or other Toshiba Medical Systems' products, please call toll free 800-421-1968, in California call (714) 730-5000 or write Toshiba Medical Systems, 2441 Michelle Drive, Tustin, CA 92680.

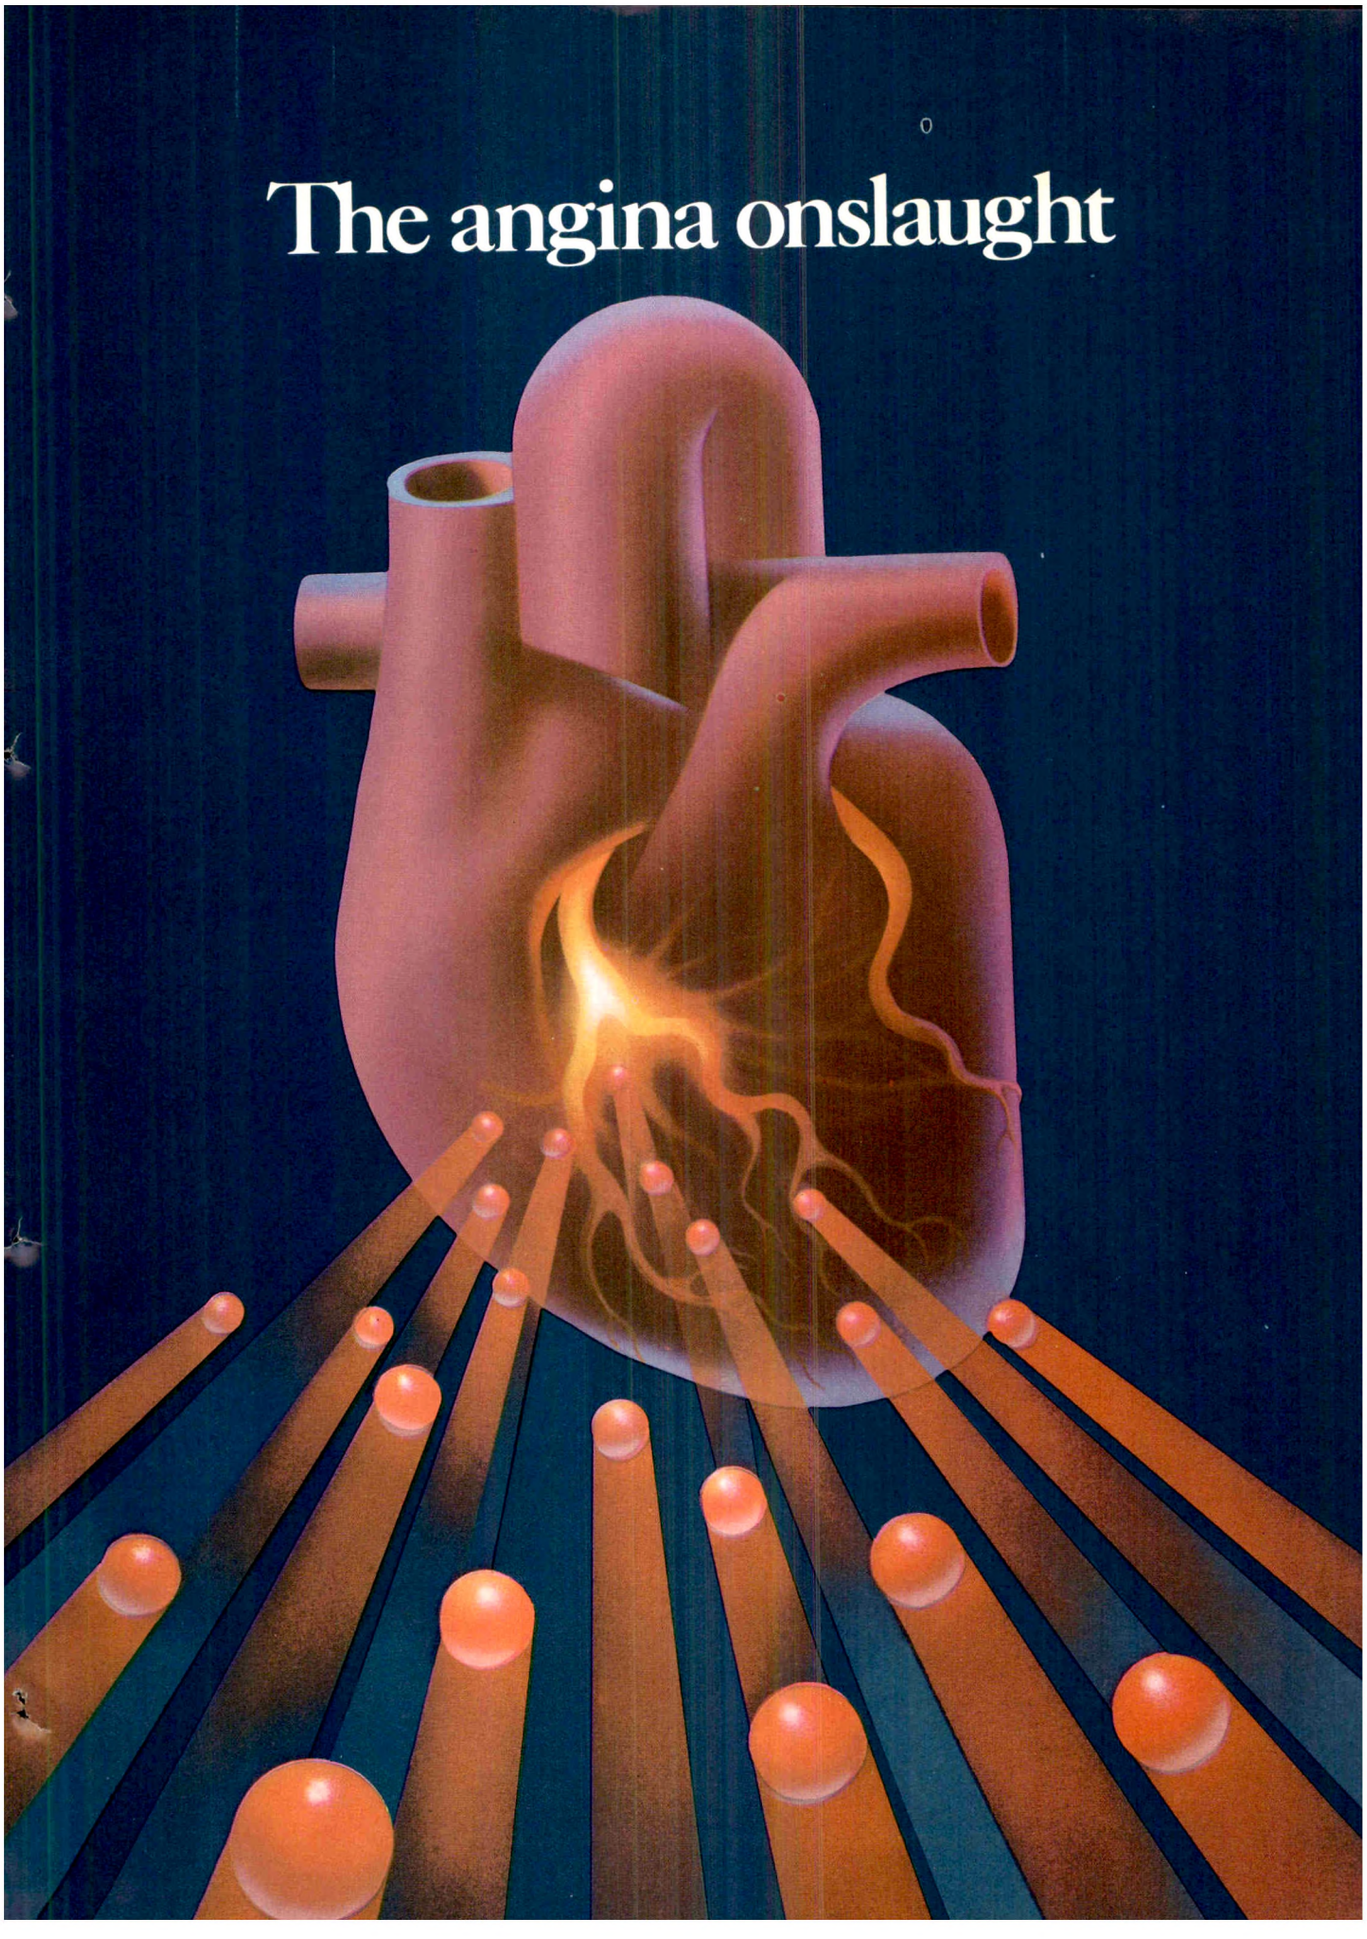
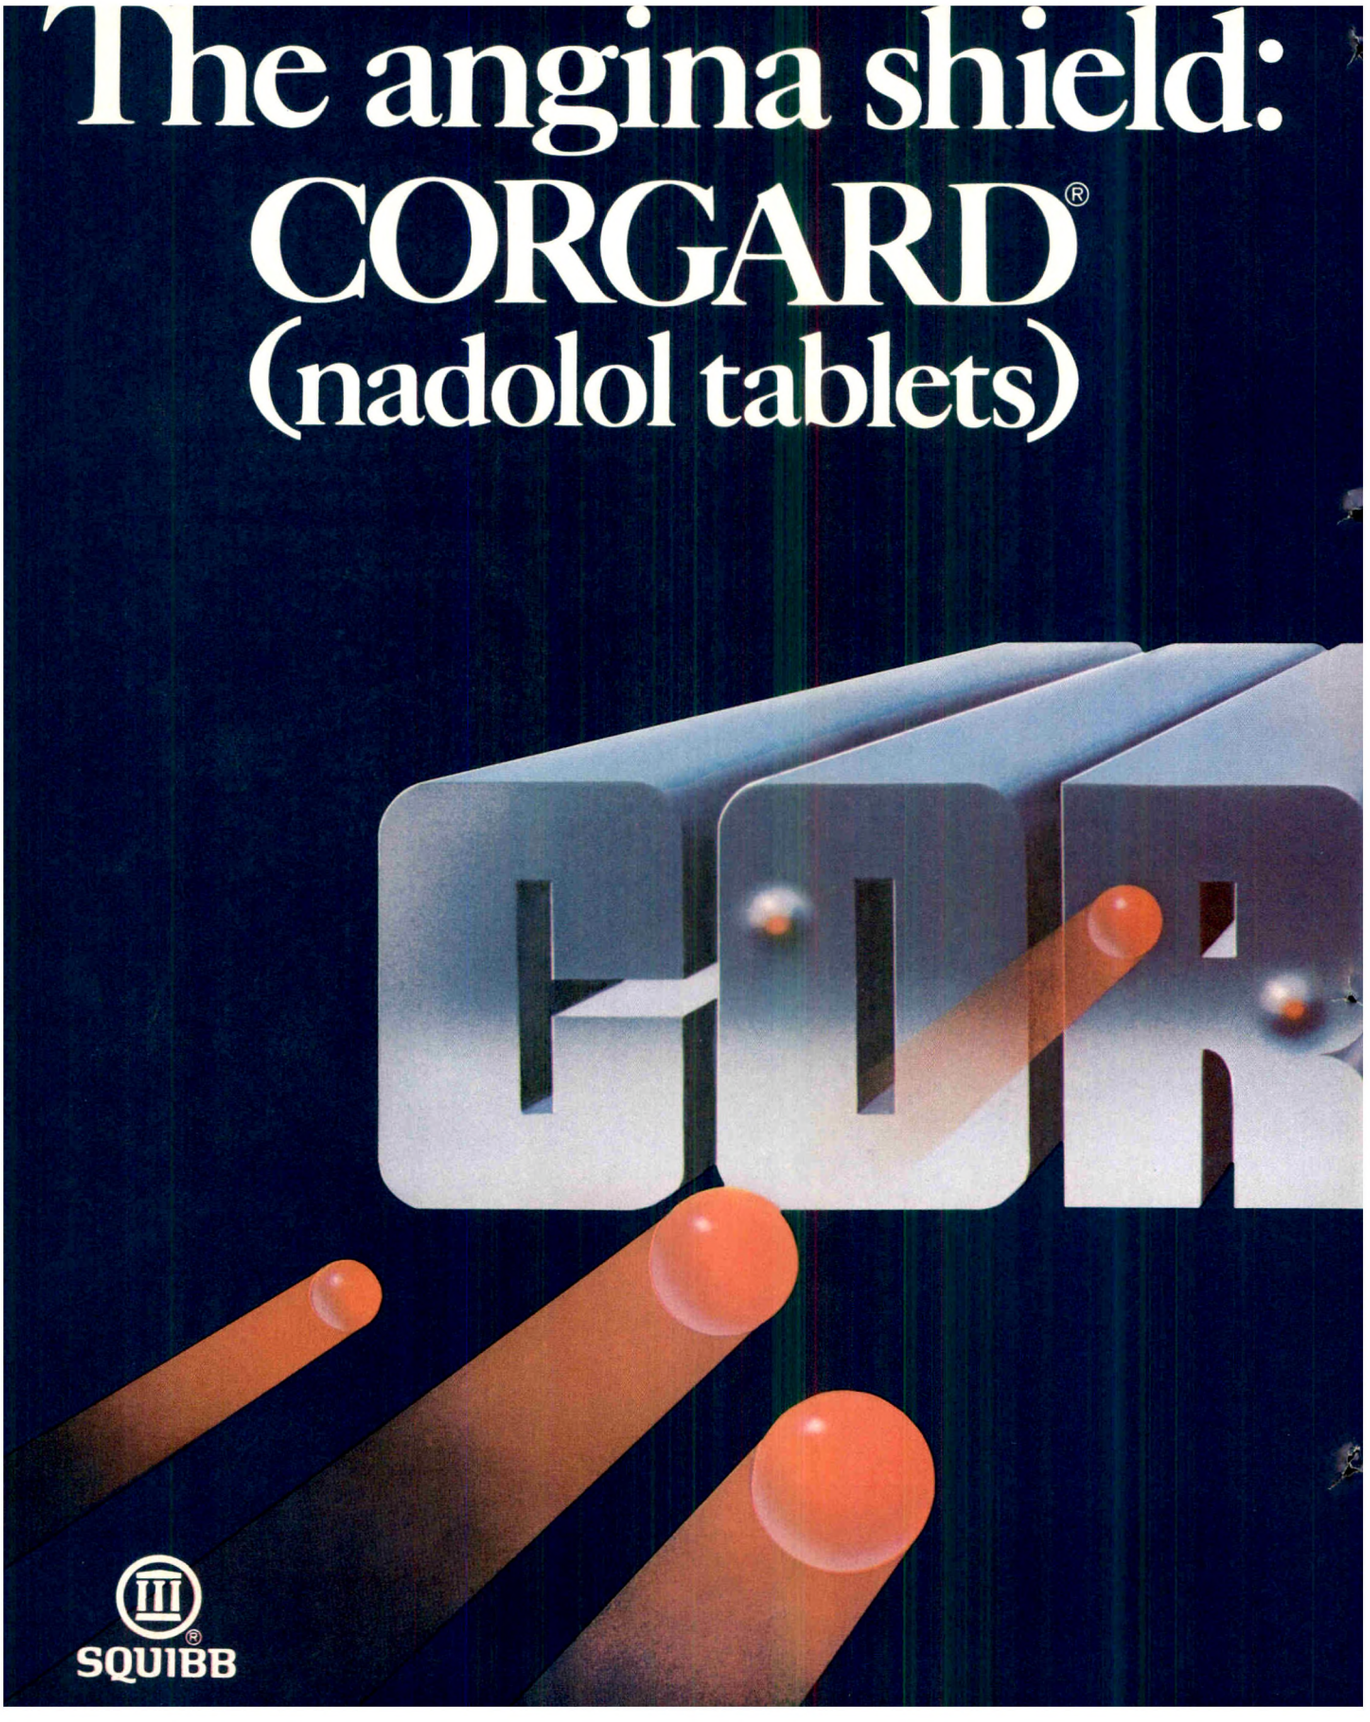
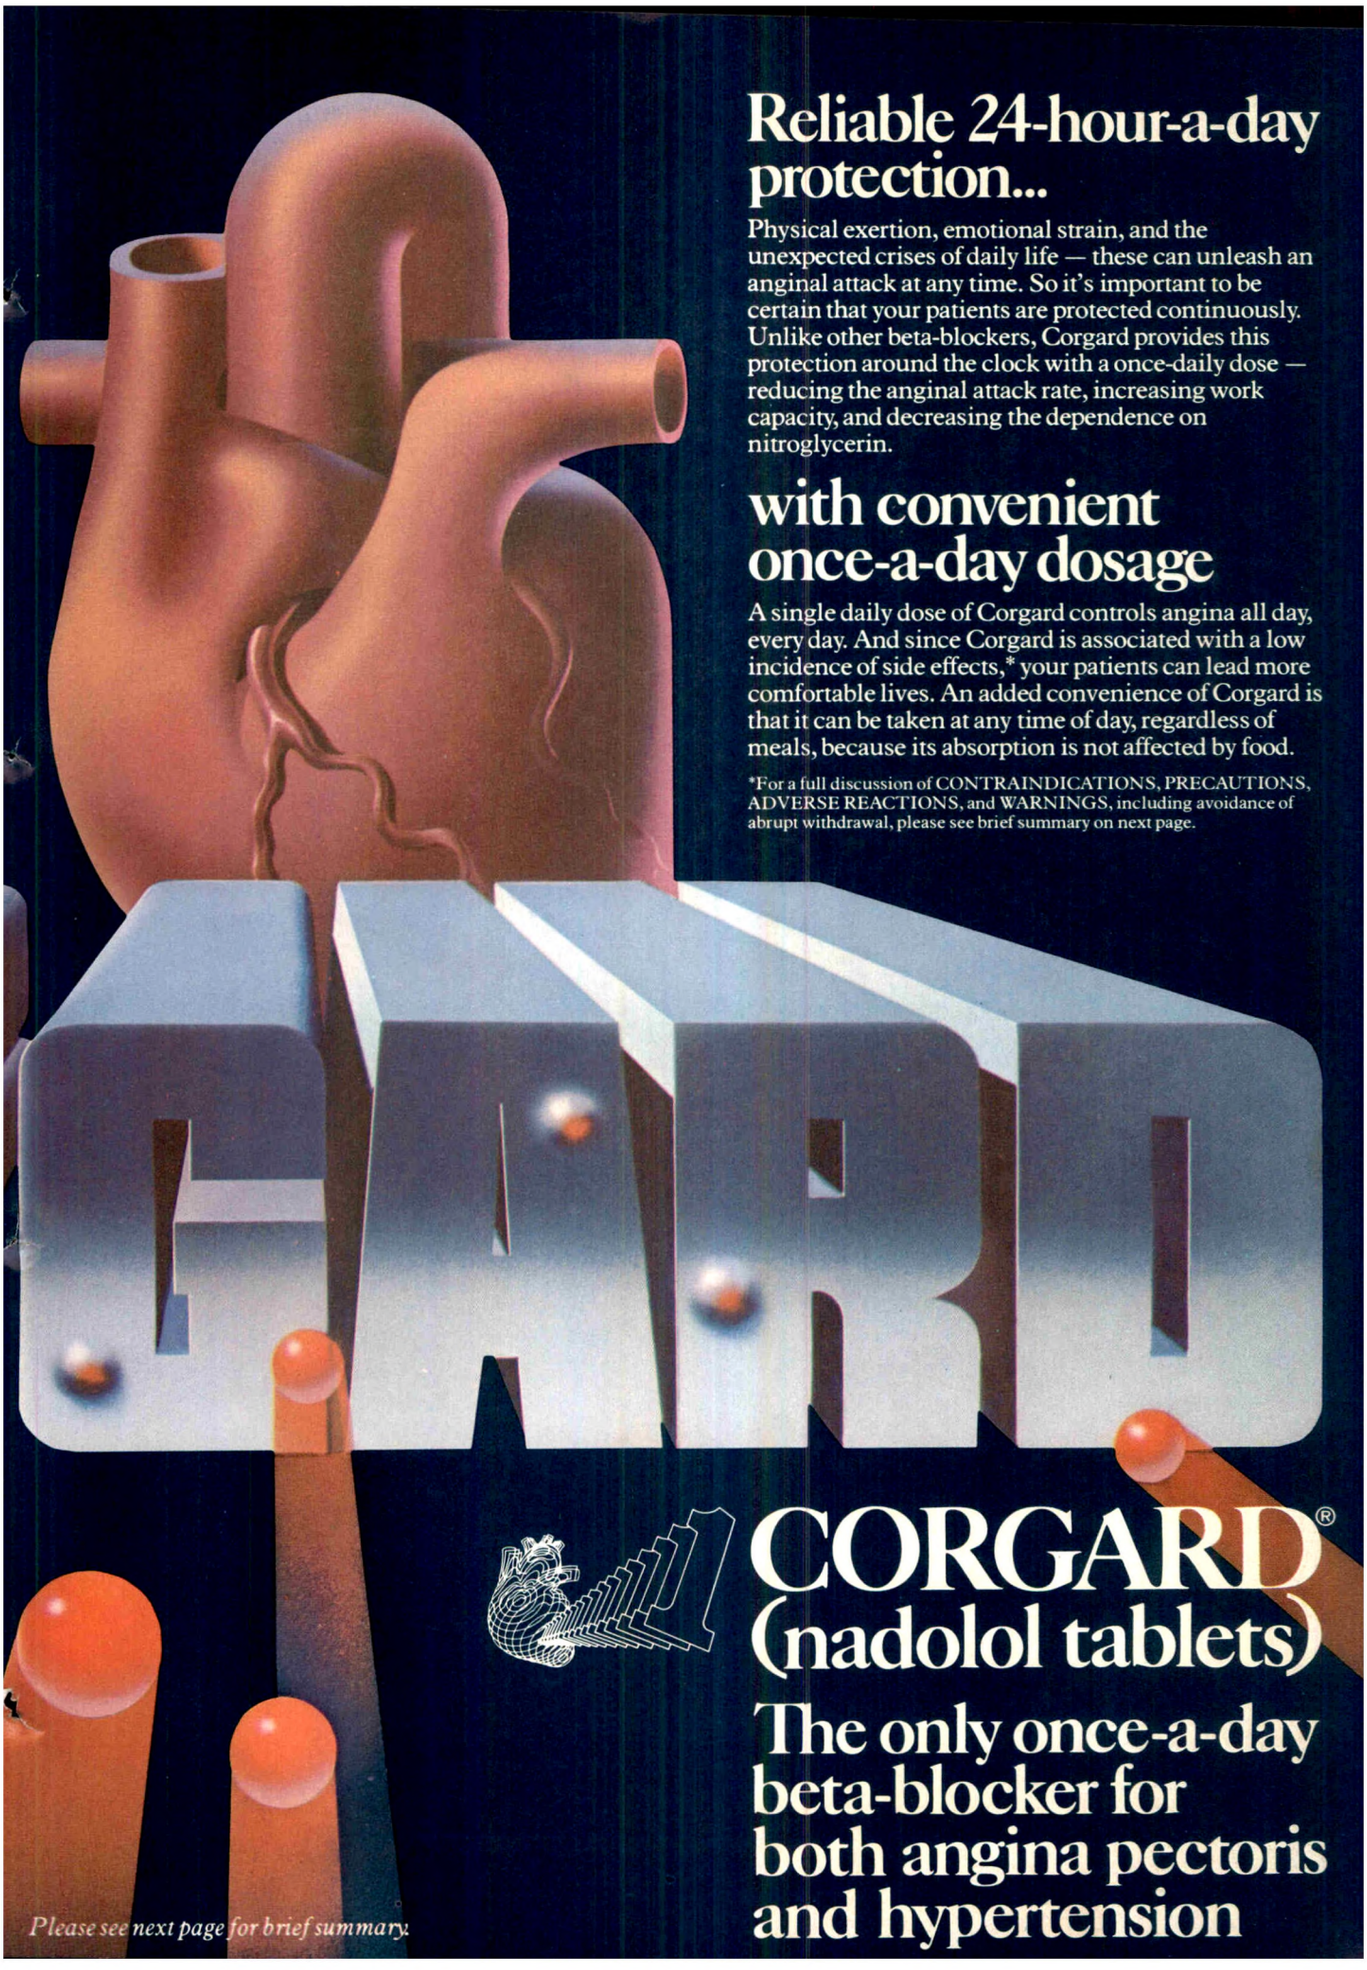
The angina onslaught



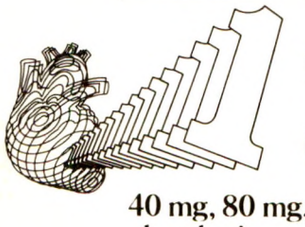
The angina shield:
CORGARD®
(nadolol tablets)





Reliable 24-hour-a-day protection...
Physical exertion, emotional strain, and the unexpected crises of daily life — these can unleash an anginal attack at any time. So it's important to be certain that your patients are protected continuously. Unlike other beta-blockers, Corgard provides this protection around the clock with a once-daily dose — reducing the anginal attack rate, increasing work capacity, and decreasing the dependence on nitroglycerin.
with convenient once-a-day dosage
A single daily dose of Corgard controls angina all day, every day. And since Corgard is associated with a low incidence of side effects,* your patients can lead more comfortable lives. An added convenience of Corgard is that it can be taken at any time of day, regardless of meals, because its absorption is not affected by food.
*For a full discussion of CONTRAINDICATIONS, PRECAUTIONS, ADVERSE REACTIONS, and WARNINGS, including avoidance of abrupt withdrawal, please see brief summary on next page.
CORGARD®
(nadolol tablets)
The only once-a-day beta-blocker for both angina pectoris and hypertension
Please see next page for brief summary.

The only once-a-day beta-blocker for both angina pectoris and hypertension



CORGARD® (nadolol tablets)

40 mg, 80 mg, 120 mg, and 160 mg scored tablets available in a variety of bottle sizes and in Convenience Packages of 40 mg and 80 mg tablets

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure — Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery — Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

Nursing Mothers — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

Pediatric Use — Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System —** Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory —** Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal —** Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous —** Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

Potential Adverse Effects: Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System —** reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal —** mesenteric arterial thrombosis; ischemic colitis. **Hematologic —** agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic —** fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous —** reversible alopecia; Peyronie's disease; erythematous rash.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm — Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most patients respond to 160 mg or less daily). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets. The 40 mg and 80 mg tablets are also available in convenience packages containing 4 blister cards of 7 tablets each.

Acute Hemodynamic Effects of Endralazine: A New Vasodilator for Chronic Refractory Congestive Heart Failure

ARSHED A. QUYYUMI, MB, MRCP, DONALD WAGSTAFF, and THOMAS R. EVANS, FRCP

Invasive hemodynamic measurements were made in 10 supine patients with chronic refractory congestive heart failure (CHF) due to ischemic heart disease or cardiomyopathy before and after oral administration of a new arteriolar vasodilator, endralazine. In 9 patients, a 10 mg dose of endralazine produced maximal increases in cardiac and stroke volume indexes of 56 and 41%, respectively, with a 45% reduction in total systemic resistance. After a 5 mg dose of endralazine, cardiac index increased maximally by 38% and stroke volume index by 34%, with a 31% decrease in total systemic resistance. Mean arterial pressure decreased 11 ± 4 mm Hg (mean ± standard error of mean) with the 5 mg dose and 17 ± 5 mm Hg after the 10 mg dose. There were no significant changes in the right atrial, pulmonary arterial, or pulmonary capillary wedge pressures. After administration of a single dose of endralazine, statistically significant hemodynamic changes were observed from 1 to 8 hours with peak responses at 3 to 4 hours. These observations suggest that endralazine has hemodynamic properties similar to those of its structural analog, hydralazine. However, endralazine metabolism is largely independent of the patients' acetylator status, and no cases of systemic lupus erythematosus have been reported after long-term oral administration. These findings suggest that endralazine may be an efficacious drug that is potentially safer than hydralazine in the treatment of chronic CHF.

Many studies have demonstrated the beneficial effects of vasodilators in chronic refractory congestive heart failure (CHF).[1–11] Several drugs are now available for clinical use, but all have major disadvantages. Long-acting nitrates reduce left ventricular filling pressure and are safe to administer but have a minimal effect on cardiac output.[6] Prazosin, a powerful arteriolar vasodilator, is associated with development of tolerance,[7,8] and minoxidil can cause hirsutism.[9,12] The dose of oral hydralazine required to produce optimal hemodynamic effects varies widely,[13] dependent in part on the patients' acetylator status. The incidence of antinuclear factor conversion at higher dose levels of hydralazine increases,[14–16] and a recent study suggested that tolerance to hydralazine may develop after long-term administration.[17] The search for alternative vasodilator agents largely free of serious side effects therefore continues.

From the Royal Free Hospital and School of Medicine, London, England. Manuscript received July 14, 1982; revised manuscript received December 21, 1982, accepted December 22, 1982.

Address for reprints: Arshed A. Quyyumi, MB, MRCP, Cardiology Registrar, National Heart Hospital, Westmoreland Street, London, W1M 8BA, England.

Endralazine (BQ22-708) is 6 benzoyl-3-hydrazino-5,6,7,8-tetrahydropyrido-4,3-c pyridazine mesilate.[18,19] It is structurally related to hydralazine (Fig. 1). Endralazine is metabolized chiefly by combination with endogenous ketones to form hydrazones.[20] These reactions are completely independent of the patient's acetylator status.[21,22] Several studies[20–25] in hypertensive patients have demonstrated the efficacy of endralazine as a powerful arteriolar dilator. No hypertensive patients treated with endralazine for up to 3 years have developed systemic lupus erythematosus.[20] Endralazine appears to have potentially less toxicity and a narrower effective dose range than many other vasodilators. This study was undertaken to determine its acute effects when administered orally to patients in chronic refractory CHF.

Methods

Patients: Ten patients, 9 men and 1 woman (age range 36 to 75 years [mean 62]) with chronic CHF of >3 months' duration, were studied. Nine patients had CHF secondary to proven ischemic heart disease demonstrated by coronary arteriography or documented previous myocardial infarction. One patient had alcoholic cardiomyopathy. Nine patients had sinus rhythm, 1 had atrial fibrillation (Patient 8), and 1 (Pa-

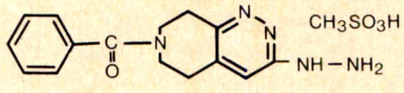
tient 7) had moderate mitral regurgitation. All patients were taking increasing doses of diuretic drugs with or without digoxin and vasodilators over the preceding months. Six patients were in New York Heart Association[26] class III and 3 were in class IV.

Hemodynamic measurements: A thermodilution pulmonary arterial catheter (model 7Fr, Instrumentation Laboratories) was introduced percutaneously through the subclavian vein under fluoroscopic control. Arterial pressure was measured directly with a soft Teflon® (Abbocath-T intravenous #21) radial artery cannula. Cardiac output was measured in triplicate using the thermodilution technique with Instrumentation Laboratories Cardiac Output Computer 701 and an ISCI/OMP-powered injector. Pressures were measured using a Hewlett-Packard monitor and transducers, and mean pressures integrated electronically. After all invasive procedures were completed, hemodynamic measurements were made at 15-minute intervals until 2 consecutive readings were obtained with a variation of <10%. These measurements included heart rate (HR), mean arterial pressure (AP), mean pulmonary arterial (PA), mean pulmonary capillary wedge (PCWP), and mean right atrial (RAP) pressures, and cardiac output (CO).

ENDRALAZINE: BQ 22-708

Chemical structure:

6-benzoyl-3-hydrazino-5,6,7,8-tetrahydropyrido-(4,3-c)-pyridazine mesylate



Molecular formula:

$C_{14}H_{15}N_3SO_3H$

HYDRALAZINE:

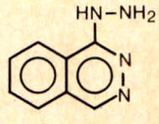


FIGURE 1. Molecular structure of endralazine and hydralazine.

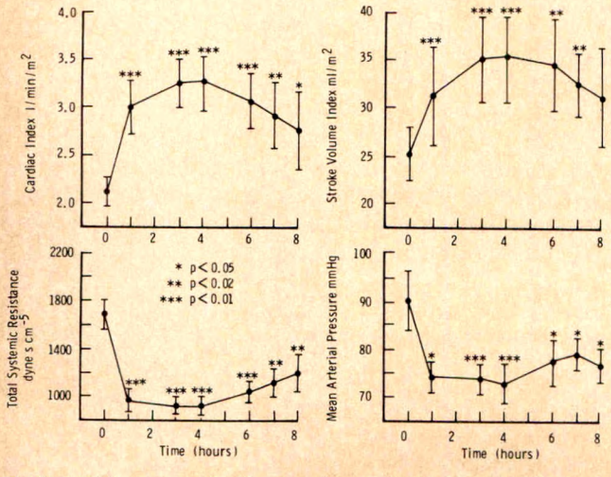

FIGURE 2. Hemodynamic changes observed with 10 mg oral dose of endralazine.

Hemodynamic variables were derived as follows: Cardiac index (liters·min^{-1} m^{-2}) = cardiac output ÷ body surface area; stroke volume index (ml·min^{-1} m^{-2}) = (cardiac index ×1,000) ÷ HR; total systemic resistance (dynes s cm^{-5}) = 80 × (mean AP − mean RAP) ÷ CO; total pulmonary resistance (TPR) (dynes s cm^{-5}) = 80 × (mean PA) ÷ CO; pulmonary arteriolar resistance (PAR) (dynes s cm^{-5}) = 80 × (mean PA − mean PCWP) ÷ CO; stroke work index (SWI) (g − m·m^{-2}) = SVI (AP − PCWP) × 0.0136.

Statistical analysis was performed using the Wilcoxon matched-pairs signed-rank test.

Drug administration: Two days before the study, all diuretic agents and vasodilators were stopped but digoxin was given at the end of the study each day. Nine patients were given a 10 mg dose of endralazine orally after food following baseline hemodynamic measurements. The patients remained supine throughout the study, hemodynamic measurements being made at 1, 3, 4, 5, 6, and 8 hours after drug administration. One of the 9 patients (Patient 2) had measurements made over 4 hours only. The following day, 9 patients (Patients 1, 2, and 4 to 10; Table I) received a 5 mg dose of endralazine orally, and measurements were made for at least 4 hours at hourly intervals. The study was discontinued at 4 hours because previous experience with the 10 mg dose had shown maximal effect at 3 to 4 hours. In 4 patients (Patients 1, 2, 5, and 6) there was no significant difference between the hemodynamic changes observed with the 5 mg dose compared with the 10 mg dose. Therefore these patients were given a 2.5 mg dose of oral endralazine and hemodynamic measurements were made over the next 4 hours.

Results

After administration of 10 mg of endralazine in 9 patients, significant increases in cardiac output and stroke volume were evident within 1 hour, with concomitant decreases in total systemic resistance (Fig. 2). The effect was maximal 3 to 4 hours after the dose, remaining significant even after 8 hours (Table I, Fig. 2). The 5 mg dose in 9 patients produced slightly smaller but similar significant changes (Table II, Fig. 3). The

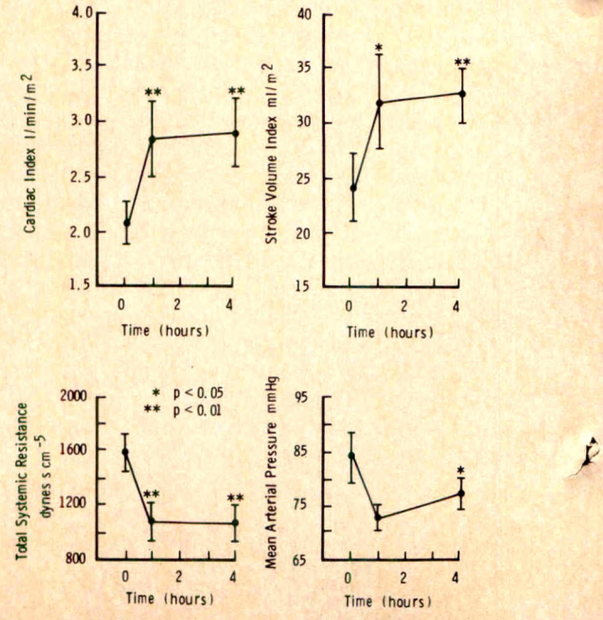

FIGURE 3. Hemodynamic changes observed with 5 mg oral dose of endralazine.

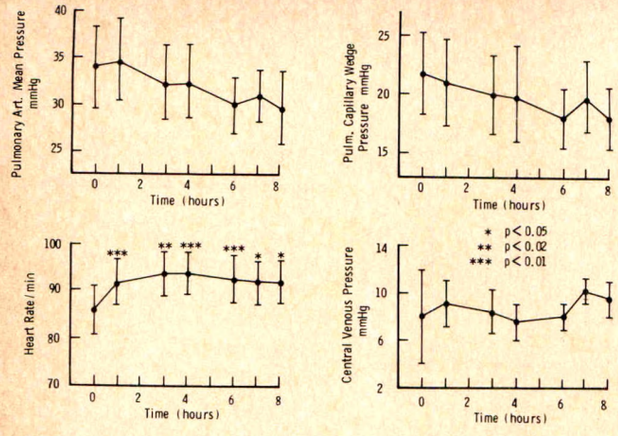

FIGURE 4. Hemodynamic changes observed with 10 mg oral dose of endralazine. Art. = arterial; Pulm. = pulmonary.

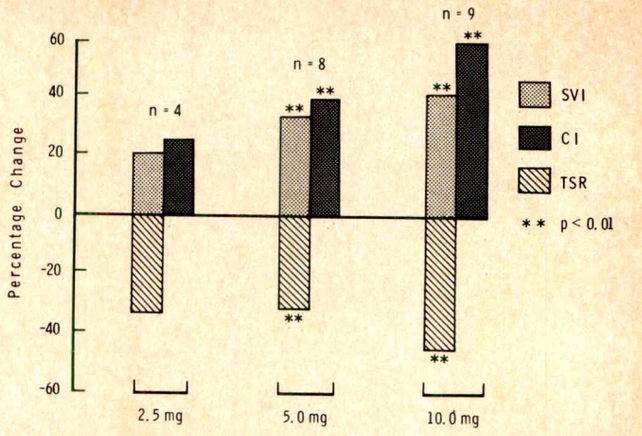

FIGURE 5. Percent hemodynamic changes observed with 2.5, 5, and 10 mg oral doses of endralazine. CI = cardiac index; SVI = stroke volume index; TSR = total systemic resistance.

decrease in mean arterial pressure and the increase in heart rate were significantly smaller with the 5 mg dose. No significant changes occurred in pressures in the right side of the heart (Fig. 4). Four patients receiving a 2.5 mg dose demonstrated smaller increases in cardiac and stroke volumes, but changes in arterial pressure and heart rate were insignificant (Fig. 5).

Discussion

Endralazine has been extensively evaluated in animal studies and has been demonstrated to have powerful arteriolar dilating action.[20,27,28] In hypertensive patients, endralazine has been found to reduce blood pressure as effectively as hydralazine and prazosin.[19,21,25] On a weight-for-weight basis it is approximately 4 to 5 times as potent as hydralazine.[20,28]

Hemodynamic changes were noted with doses ranging from 2.5 to 10 mg. Most patients achieved considerable hemodynamic improvement with the 5 mg dose of endralazine. In 2 patients (Patients 6 and 7) the 10 mg dose of endralazine produced a marked decrease in arterial pressure and increase in heart rate denoting excessive vasodilatation. Patients who were initially hypertensive (Patients 1 and 7) also had a greater than average reduction in mean arterial pressure. The patients who received the 2.5 mg dose of endralazine showed a smaller decrease in systemic resistance and a smaller increase in cardiac output than those receiving the larger doses (Fig. 5). These results suggest that for most patients in refractory cardiac failure, an optimal hemodynamic response with minimal adverse effects will be obtained with the 5 mg dose of endralazine (Table II). Oral endralazine is rapidly absorbed, with obvious hemodynamic effects within 1 hour of administration reaching a maximum at 3 to 4 hours. The plasma half-life of endralazine is much longer than that of hydralazine, and in hypertensive patients a twice-daily dose may provide adequate control.[20] Fixation to vessel walls and subsequent slow release may explain the prolonged in vivo action of hydralazine,[29–31] and a similar phenomenon has been demonstrated using carbon-14–labeled endralazine in animals.[20]

Several studies in hypertension[20–22] have clearly shown that acetylator status has no effect on the dose of endralazine required, whereas it profoundly influences the dose of hydralazine needed for a therapeutic effect[16]: this is an important advantage of endralazine, which will have a narrower dose range than hydralazine.

Throughout this study patients remained supine and no adverse effects were noted. No patient had any hypotensive symptoms, and only 1 patient experienced facial flushing with a 10 mg and not with a 5 mg dose of endralazine. Long-term studies in hypertensive patients have confirmed the absence of serious side effects or tolerance.[20,22,24] Flushing and edema were the most commonly noticed adverse effects, the latter responding to the addition of a diuretic drug. None of the 224 patients treated for approximately 1 year had any clinical manifestations of systemic lupus erythematosus.[20] Two patients had significant antinuclear antibody titres in the serum, but there were no increases in these levels with continuation of endralazine therapy. The hydrazine radical on both the molecules of hydralazine and endralazine is thought to be immunogenic when combined with collagen.[32] The difference in metabolism of the 2 drugs and the higher potency of endralazine minimizes the exposure of the hydrazine radical to collagen even after prolonged treatment.

Endralazine is an orally effective powerful arteriolar dilator and after acute administration in this study it has been shown to produce an increased cardiac output in patients with chronic refractory CHF. It has no significant venodilating action. Essentially 3 factors limit the usefulness of hydralazine in some patients with chronic CHF: (1) the wide variability in the dose of hydralazine required for therapeutic effect,[13] (2) the risk of developing systemic lupus erythematosus at larger dose levels,[14–16] and (3) tolerance after long-term treatment.[17] Endralazine, which has a different metabolism, appears superior to hydralazine for at least 2 reasons. Unless tolerance to endralazine develops on long-term therapy, its narrower dose range and freedom

from immunologic side effects suggest it is safer and potentially superior to hydralazine. Long-term studies to evaluate the sustained efficacy of endralazine in refractory CHF at rest and on exercise are required and are being undertaken at this center.

Exercise Intolerance in Patients With Chronic Left Heart Failure: Relation to Oxygen Transport And Ventilatory Abnormalities

JOHN R. WILSON, MD and NANCY FERRARO, RN

Circulatory, metabolic, and ventilatory responses to maximal and submaximal symptom-limited exercise were studied in 13 patients with chronic stable heart failure. Maximal exercise was sustained 6.5 ± 0.6 minutes (mean ± standard error of the mean) and increased minute oxygen consumption ($\dot{V}O_2$) to 940 ± 65 ml/min, whereas submaximal exercise was sustained for 15.4 ± 2.3 minutes and increased $\dot{V}O_2$ to 825 ± 49 ml/min (both $p < 0.01$ compared with maximal exercise). Both exercise protocols were terminated because of fatigue and both were associated with reduced cardiac output relative to $\dot{V}O_2$, marked systemic oxygen extraction (80 ± 2% maximal versus 78 ± 2% submaximal) and similarly elevated blood lactate concentrations (37 ± 4 mg/dl maximal versus 36 ± 4 mg/dl submaximal), suggesting inadequate oxygen delivery to working muscle. Minute ventilation during both types of exercise was also more than twice normal relative to carbon dioxide production. However, during submaximal exercise, dyspnea was noted in only 3 patients despite these ventilatory abnormalities. During maximal exercise, dyspnea was noted in 11 patients but did not force termination of exercise or preclude achievement of marked systemic oxygen extraction and lactate production. These data suggest that patients with chronic stable cardiac failure are limited during both maximal and submaximal exercise primarily by inadequate oxygen transport to working muscle.

Patients with chronic heart failure are frequently limited during exertion even when they have no symptoms at rest.[1–3] Several investigators have suggested that this exercise intolerance is primarily due to inadequate oxygen transport to working muscle.[3–6] This hypothesis is supported by the observation that maximal exercise in patients with chronic heart failure is associated with progressive increases in blood lactate concentration and oxygen extraction, suggesting inadequate oxygen availability in working skeletal muscle.[3,4,7]

Other investigators have suggested that the exercise intolerance of these patients may partially be due to elevated intrapulmonary pressure and exertional dyspnea,[2,8,9] particularly during normal daily activities, most of which involve submaximal exercise. During submaximal exercise, oxygen transport to working muscle may be adequate because the oxygen demands of muscle are lower than they are during maximal exercise. Submaximal exercise also can be sustained for substantially longer periods of time than maximal exercise. Therefore, intrapulmonary pressure may remain elevated much longer and may produce more severe ventilatory abnormalities and breathlessness than those observed during maximal exercise. However, whether this is the case remains uncertain because respiratory function and oxygen transport during submaximal exercise have not previously been characterized in patients with chronic heart failure.

The present study was undertaken to determine whether patients with chronic heart failure are limited during exercise by oxygen transport abnormalities or ventilatory abnormalities. We examined symptomatic, metabolic, and ventilatory responses to both maximal and submaximal exercise in patients with chronic stable heart failure due to left ventricular dysfunction. We postulated that if exercise is limited by inadequate oxygen transport to working muscle, termination of exercise would be associated with exhaustion and metabolic evidence of inadequate muscle perfusion. Alternatively, if exercise is limited by the respiratory system, termination of exercise would be associated with dyspnea and ventilatory abnormalities without metabolic evidence of inadequate muscle perfusion.

Methods

Patients: Thirteen men with chronic functional class III heart failure and left ventricular dysfunction (ejection fraction 24 ± 7%) were studied (Table I). The mean age was 55 ± 5 years. All patients had a history of exertional fatigue despite the administration of digoxin and diuretics. All patients had a clinically stable condition with no history of worsening heart failure or a change in cardiac medication for 2 months; pe-

* $p < 0.05$ compared with maximal exercise.
† $p < 0.01$ compared with maximal exercise.
AVO_2 = arteriovenous oxygen difference; BP = blood pressure; CO = cardiac output; Ext = extraction; HR = heart rate; PAP = pulmonary arterial pressure; PWP = pulmonary wedge pressure; $\dot{V}E$ = minute ventilation; $\dot{V}O_2$ = minute oxygen consumption.

ripheral edema, ascites, and pulmonary rales were not present at the time of the study. Left ventricular dysfunction was attributed to coronary disease in 8 patients and to idiopathic cardiomyopathy in 5.

Protocol: To acquaint the patient with the exercise protocol, trial maximal and submaximal exercise tests were performed the day before study. Exercise was performed on an upright bicycle ergometer (Monarch). For maximal exercise testing, exercise was begun at a work load of 20 W and increased every 3 minutes by 20 W to a symptomatic maximal level. Submaximal exercise testing was performed at 50% of the maximal work load.

The following day, a triple-lumen Swan-Ganz catheter was inserted through an antecubital vein and positioned in the pulmonary artery. A short polyethylene catheter was inserted in a radial artery. Twenty minutes after instrumentation, maximal exercise testing was performed. Resting oxygen consumption was measured continuously for 5 to 10 minutes before exercise and throughout exercise. Pulmonary artery and wedge pressure was recorded and pulmonary artery and arterial blood samples for oxygen saturation and lactate concentration were obtained at rest, 2.5 minutes into each stage of exercise, and at maximal exercise. Arterial blood samples for pH and partial pressure of carbon dioxide and

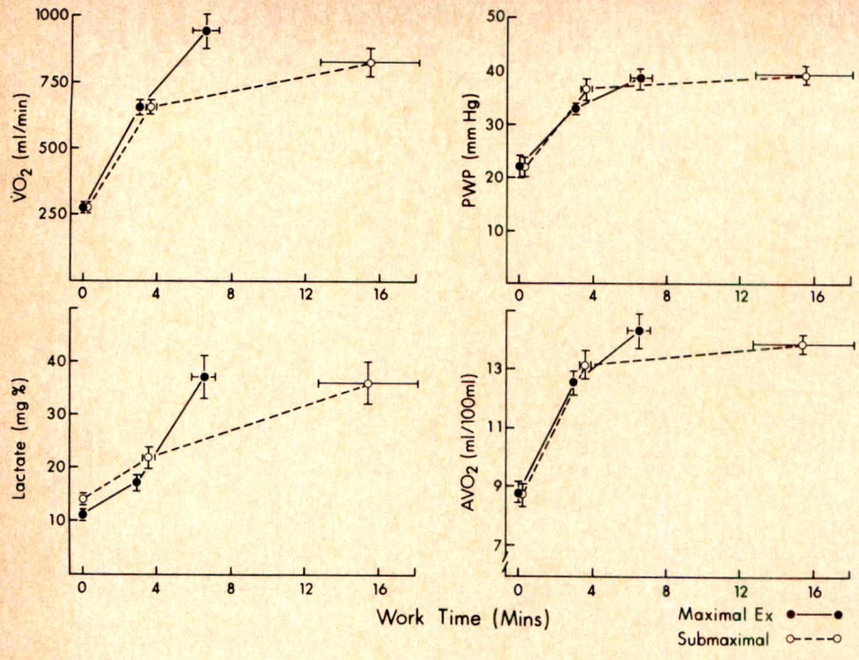

FIGURE 1. Effect of maximal and submaximal exercise (Ex.) on minute oxygen consumption ($\dot{V}O_2$), pulmonary wedge pressure (PWP), lactate, and arteriovenous oxygen difference (AVO_2). Mean ± standard errors are given at rest, for the first sampling period, and at peak exercise.

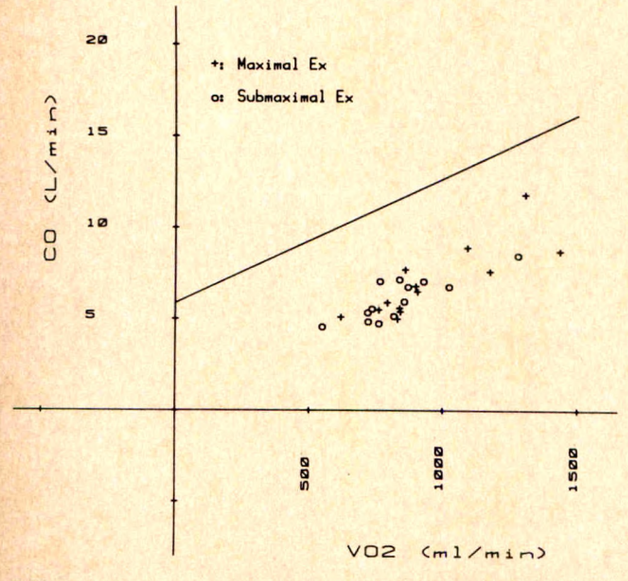

FIGURE 2. Relation of cardiac output (CO) to $\dot{V}O_2$ at peak maximal (+) and submaximal (0) exercise. The normal cardiac output response is indicated by the **solid line**.[26]

oxygen were obtained at rest and at maximal exercise in 9 patients.

After a 2-hour period of rest, submaximal exercise was performed at a fixed work load of 50% of the maximal work load achieved earlier in the day. Respiratory measurements were taken as noted previously. Hemodynamic measurements and blood samples were obtained at 3- or 4-minute intervals depending on the expected exercise duration. In 3 patients, pulmonary wedge pressure could not be obtained after initial baseline recordings. In these patients, pulmonary wedge pressure was estimated from pulmonary artery diastolic pressure by subtracting the resting pulmonary artery diastolic-wedge pressure gradient.

Measured variables: Minute oxygen consumption ($\dot{V}O_2$), minute carbon dioxide production ($\dot{V}CO_2$), and minute ventilation ($\dot{V}_E$) were measured with a Beckman metabolic cart equipped with a Beckman OM-11 oxygen analyzer, Beckman LB-2 carbon dioxide analyzer, and a volume transducer. Respiratory gases were delivered first to a mixing chamber and then to a volume transducer and gas analyzer. Total expired volume and the average oxygen and carbon dioxide concentrations of expired gas were calculated every 30 seconds by a Model 1810 Monroe programmable calculator and used to calculate $\dot{V}CO_2$ and $\dot{V}O_2$. Results were printed on tape. Resting values reported represent the mean of values obtained over 5 to 10 minutes. The gas analyzers were calibrated at the beginning of each study with a 4% carbon dioxide/16% oxygen balanced nitrogen calibration gas.

Mean blood pressure was obtained by electronic integration of the phasic arterial pressure tracing. Arterial blood for lactate determination was deproteinized with cold perchloric acid and assayed with a spectrophotometric technique. Hemoglobin concentration was measured by a Coulter counter. Hemoglobin oxygen saturation was measured by a co-oximeter (Instrumentation Laboratories) precalibrated with human blood. Blood oxygen content was calculated as follows: hemoglobin × 1.34 ml oxygen/gram hemoglobin × percent oxygen saturation. Arteriovenous oxygen difference was calculated as arterial-pulmonary artery oxygen content. Oxygen extraction was calculated as the arteriovenous oxygen difference/arterial oxygen content. Cardiac output was calculated by the Fick principle as $\dot{V}O_2$/arteriovenous oxygen difference.

Statistical methods: Statistical analysis was performed by Student's *t* test for paired or unpaired data, as appropriate. Linear regression analysis was performed using the least-squares method. Data are expressed as mean ± standard error. A p value <0.05 was considered statistically significant.

Results

Results of this study are summarized in Table I and Figures 1 to 4. During maximal exercise, the peak work load achieved averaged 51 ± 16 W (range 20 to 80).

Submaximal exercise was performed at an average work load of 25 ± 8 W (range 10 to 40).

Maximal exercise: Maximal exercise was sustained for 6.5 ± 0.6 minutes and increased $\dot{V}O_2$ from 271 ± 13 to 940 ± 65 ml/min, cardiac output from 3.1 ± 0.1 to 6.7 ± 0.6 liters/min, and pulmonary wedge pressure from 22 ± 2 to 38 ± 2 mm Hg (Fig. 1). The peak cardiac output was reduced in all patients relative to $\dot{V}O_2$ (Fig. 2).[10,11] Exercise produced progressive elevations in lactate (11 ± 1 to 37 ± 4 mg/dl) and marked oxygen extraction (49 ± 2 to 80 ± 2%) (Fig. 1), consistent with inadequate oxygen delivery to working muscle. Exercise was terminated by leg fatigue in all patients, although 11 patients also reported moderate to severe dyspnea.

Minute ventilation during exercise was linearly related to $\dot{V}CO_2$ in all patients (r = 0.96 to 0.99) (Fig. 3). The slopes of these relations (0.051 ± 0.015 [mean ± standard deviation]) were nearly twice those reported in normal subjects (0.023 ± 0.005),[12,13] indicating both excessive ventilatory levels and increased ventilation of anatomic or physiologic dead space, or both.[14] Ventilatory levels were also excessive relative to $\dot{V}O_2$. Up to 20 to 50% of maximal $\dot{V}O_2$, minute ventilation was linearly related to $\dot{V}O_2$ with a slope of 0.051 ± 0.013 versus of 0.022 ± 0.012 in normal subjects.[12,13–15] At levels of $\dot{V}O_2$ above 50% of the maximal $\dot{V}O_2$, minute ventilation increased out of proportion to increases in $\dot{V}O_2$ because of buffering of lactate by bicarbonate and consequent release of carbon dioxide.[3,8,14]

Exercise increased the arterial pO_2 (98 ± 5 to 108 ± 7 mm Hg [$p < 0.01$]), decreased arterial pCO_2 (31 ± 2 to 27 ± 2 mm Hg [$p < 0.01$]), whereas pH remained unchanged (7.48 ± 0.01 to 7.47 ± 0.02 [p not significant]) (Fig. 4).

Submaximal exercise: In all patients, submaximal exercise was sustained substantially longer than maximal exercise (15.4 ± 2.3 minutes). Oxygen uptake in-

creased rapidly with the onset of exercise, thereafter increasing at a lesser pace. At the termination of exercise, both cardiac output and $\dot{V}O_2$ were significantly lower than during maximal exercise (6.0 ± 0.3 liters/min and 825 ± 49 ml/min, respectively). Peak cardiac output was reduced in all patients relative to $\dot{V}O_2$, as during maximal exercise (Fig. 2).

Despite lower work loads and oxygen uptake than those during maximal exercise, submaximal exercise produced progressive increases in blood lactate (14 ± 1 to 36 ± 4 mg/dl) and oxygen extraction (49 ± 2 to 78 ± 2%), suggesting inadequate oxygen availability in working muscle. Levels increased less rapidly than during maximal exercise (Fig. 1). However, exercise was terminated when lactate concentrations and oxygen extraction achieved levels comparable to those noted at termination of maximal exercise. Exercise was terminated by fatigue in all patients, with only 3 patients reporting moderate dyspnea.

Despite the lower incidence of symptomatic dyspnea than that during maximal exercise, pulmonary wedge pressure increased as rapidly as during maximal exercise (22 ± 2 to 39 ± 2 mm Hg) and remained elevated substantially longer (Fig. 1). However, the relation of minute ventilation to $\dot{V}O_2$ and $\dot{V}CO_2$ was comparable to that noted during maximal exercise; minute ventilation was linearly related to $\dot{V}O_2$ ($r = 0.94$ to 0.99) with a slope of 0.051 ± 0.016 (mean ± standard deviation) and to $\dot{V}CO_2$ ($r = 0.96$ to 0.99) with a slope of 0.052 ± 0.013 (Fig. 3). Peak minute ventilation reached was actually less than that during maximal exercise because of the lower levels of $\dot{V}O_2$ and $\dot{V}CO_2$ achieved. Changes in arterial blood gases during submaximal exercise were similar to those noted during maximal exercise (Fig. 4).

Discussion

Patients with chronic heart failure are frequently limited during exercise.[1–3] Recently, there has been great interest in identifying pharmacologic methods of improving the exercise capacity of such patients. To attain this objective, the mechanism responsible for the reduced exercise capacity must be identified. Accordingly, the present study was undertaken to investigate the mechanism of exercise intolerance in a specific subgroup of patients with heart failure, those with clinically stable, chronic heart failure who are without evidence of pulmonary alveolar or peripheral edema. Submaximal as well as maximal exercise was studied because most normal daily activities performed by such patients involve submaximal exercise. Work loads (10 to 40 W) undertaken during submaximal exercise protocols in the present study are equivalent to walking and housework and therefore comparable to exercise levels during normal daily activity.

Exercise limitation and oxygen transport: The results of the present study suggest that both submaximal and maximal exercise capacity of such patients is limited by the same factor: inadequate oxygen transport to working muscle. During both levels of exercise, exhaustion was the principal limiting symptom whether or not dyspnea was present. During both exercise protocols, progressive increases in blood lactate occurred, indicating inadequate oxygen availability in working muscle and increased anaerobic metabolic activity.[4,16,17] Moreover, submaximal and maximal exercise was terminated at nearly identical levels of lactate, suggesting that accumulation of a critical level of lactate in working muscle may have produced exhaustion by depressing muscle contractile force. In normal subjects performing exhaustive exercise of varying duration, a similar close relation between exhaustion and achievement of a critical level of lactate was noted unless exercise was extremely prolonged.[16]

The levels of oxygen extraction noted at the end of exercise further suggest that exercise was terminated because of exhaustion of oxygen transport to working muscle. During exercise, oxygen delivery to working muscle is determined by cardiac output and the capacity of muscle to extract oxygen.[18,19] These 2 factors increase simultaneously so as to optimize oxygen delivery, exhaustion of oxygen transport mechanisms coinciding with exhaustion of oxygen extraction.[18–20] In untrained normal subjects, this exhaustion occurs at a maximal oxygen extraction of 70 to 80%.[18–20] Levels of oxygen extraction in the present study were equal to or exceeded these levels when cardiac output was reduced. This finding suggests that the capacity of the circulatory system to deliver oxygen to working muscle by increasing either cardiac output or oxygen extraction was exhausted.

Previous investigators have also noted that in patients with chronic heart failure, elevated blood lactate levels, marked oxygen extraction, and a plateau in oxygen uptake frequently develop during maximal exercise.[3,4,7] They also concluded that maximal exercise capacity in patients with heart failure is limited by oxygen transport mechanisms. Therefore, our findings support this conclusion and further suggest that submaximal exercise is also limited by oxygen transport abnormalities.

Exercise limitation and ventilatory abnormalities: The other major factor that has been postulated to limit the exercise capacity of patients with heart failure is ventilatory abnormalities. Our results suggest that major abnormalities in the ventilatory response to exercise are a characteristic accompaniment of chronic cardiac failure. During both maximal and submaximal exercise, ventilatory levels were linearly related to $\dot{V}CO_2$, as in normal subjects.[12,13–15] The mean slopes of these relations were both over twice normal, indicating that more respiratory effort was expended ventilating anatomic or physiologic dead space, or both.[14] This finding is consistent with a recent preliminary report that dead space is increased during exercise in patients with chronic cardiac failure.[21] Similar ventilatory abnormalities have been described previously in patients with mitral stenosis.[22–26]

Our findings suggest, however, that these ventilatory abnormalities do not limit the exercise capacity of patients with chronic compensated heart failure. During submaximal exercise, the patients in this study usually did not report dyspnea. During maximal exercise, dy-

spnea was frequent, probably due to the development of higher levels of minute ventilation than those achieved during submaximal exercise. However, patients reported that this symptom did not cause them to terminate exercise. In support of this subjective impression, patients were invariably able to exercise to work loads that produced elevated blood lactate concentrations and marked oxygen extraction.

Moreover, the dyspnea noted during maximal exercise may actually be due to abnormal oxygen transport to working muscle. Minute ventilation characteristically increased out of proportion to oxygen uptake during the latter half of the maximal exercise protocol (Fig. 3). This disproportionate increase in minute ventilation is due to buffering of lactate by bicarbonate and consequent release of carbon dioxide.[3,8,14] If oxygen delivery to working muscle had been adequate and lactate release had not occurred, minute ventilation would have been less and dyspnea might have been markedly diminished or prevented. During submaximal exercise, minute ventilation usually did not increase out of proportion to oxygen uptake because the rate of increase in lactate was not as rapid as that during maximal exercise. Therefore, the amount of carbon dioxide released each minute by bicarbonate buffering of lactate was much lower during submaximal than during maximal exercise. Arterial hypoxemia also did not occur during either maximal or submaximal exercise, indicating that ventilatory abnormalities do not limit exercise by interfering with oxygen uptake in the lungs.

Mechanism of ventilatory abnormalities: Ventilatory abnormalities during exercise in patients with heart failure have often been attributed to acute elevations in pulmonary wedge pressure during exertion producing pulmonary congestion.[22–24] If an acute elevation in wedge pressure is the primary stimulus to excessive ventilatory patterns, the much more prolonged elevations in wedge pressure noted during submaximal exercise would be expected to produce more excessive ventilation than that produced during maximal exercise. Moreover, with progressive maximal and submaximal exercise, a progressive increase in wasted ventilation might be anticipated. We observed that ventilatory levels were linearly related to $\dot{V}CO_2$ throughout exercise and were not higher for any given $\dot{V}CO_2$ during submaximal versus maximal exercise. It appears likely that acute elevations in wedge pressure during exercise are not the primary stimulus to excessive ventilation. Alterations in respiratory function due to chronic pulmonary congestion or chronic lung damage therefore are probably the most important factor.

Clinical implications: Our data suggest that fatigue due to inadequate oxygen delivery to working muscle is the principal factor limiting the exercise capacity of patients with stable chronic left heart failure. Therefore, therapeutic efforts to improve the exercise capacity of such patients should focus primarily on altering skeletal muscle oxygen delivery during exercise. At present, relatively little information is available on the modulation of skeletal muscle flow during dynamic exercise in patients with heart failure or the effect of pharmacologic agents on oxygen delivery to working skeletal muscle. Further studies are needed in this area.

Dyspnea, however, may be an important factor limiting exercise in patients with heart failure and substantial fluid retention. In addition, dyspnea may be a hindrance to some daily activities in patients without substantial fluid retention. Patients often report that certain forms of exercise, such as climbing stairs, produce greater dyspnea than other activities. We did not examine symptomatic and metabolic responses to all types of exercise. Therefore, patients with chronic stable heart failure may be limited to some extent by dyspnea during certain daily activities. Nevertheless, our data still suggest that inadequate oxygen delivery to working muscle is the dominant limiting factor during exercise.

Hemodynamic Effects of Dibutyryl Cyclic AMP In Congestive Heart Failure

SHINOBU MATSUI, MD, EIJI MURAKAMI, MD, NOBORU TAKEKOSHI, MD, JIRO EMOTO, MD, and MUNETOSHI MATOBA, MD

To evaluate the hemodynamic effects of dibutyryl cyclic AMP (DBcAMP) in congestive heart failure (CHF), right-sided cardiac catheterization was performed in 11 patients with CHF, and hemodynamic variables were investigated before and after infusion of various doses of DBcAMP at a rate of 0.025 to 0.2 mg/kg/min (mean 0.14 ± 0.077 [standard deviation]). DBcAMP reduced total systemic vascular resistance index from 3,171 ± 1,158 to 1,880 ± 554 dynes s $cm^{-5} \cdot m^2$ (mean ± standard deviation) and pulmonary arterial end-diastolic pressure from 23 ± 13 to 20 ± 11 mm Hg, and increased cardiac index from 2.24 ± 0.60 to 3.41 ± 1.02 liters/min/m^2. Mean arterial blood pressure decreased from 91 ± 14 to 84 ± 13 mm Hg, and heart rate increased from 91 ± 16 to 99 ± 13 beats/min. The increase in cardiac index was accompanied by a proportional decrease in total systemic vascular resistance index in all patients except 1. In 8 patients the decrease in pulmonary arterial end-diastolic pressure was accompanied by an increase or no change in the left ventricular stroke work index. In 6 patients, DBcAMP was given in incremental doses of 0.05, 0.1, and 0.2 mg/kg/min every 20 minutes, and 5 of 6 patients tolerated the full dose and showed dose-related hemodynamic changes for the incremental doses of DBcAMP. These data suggest that DBcAMP has powerful vasodilating effects on resistance vessels in patients with CHF; hence, it can be a useful vasodilating agent for treatment of CHF.

Since the discovery of cyclic AMP (adenosine 3′,5′-monophosphate) by Sutherland and Rall[1] in 1958, it has been found to act as a mediator in the action of various hormones. The second messenger theory has been proposed concerning the relation between catecholamine and cyclic AMP. According to this theory, the positive inotropic effects of catecholamines result from an increase in the intracellular level of cyclic AMP produced by activation of adenyl cyclase.[2–4] However, exogenous cyclic AMP does not produce such positive inotropic action because it does not penetrate the cell membrane at a rate sufficient to achieve an effective intracellular concentration.[5] However, dibutyryl cyclic AMP (DBcAMP), a derivative of cyclic AMP, is thought to penetrate the cell membrane more easily than cyclic AMP and to be resistant to inactivation by phosphodiesterase.[6]

In a variety of studies using perfused heart-lung preparations and experimental animals, it has been shown that a relatively large amount of DBcAMP has a positive inotropic effect and a positive chronotropic effect similar to that of catecholamines.[7–12] In addition, it has been reported that DBcAMP increases renal and mesenteric arterial blood flow and decreases peripheral vascular resistance.[13] No information is available on the hemodynamic responses to DBcAMP in patients with congestive heart failure (CHF). This study was designed to examine the hemodynamic effects of DBcAMP and to evaluate the clinical efficacy of this agent in patients with CHF.

Methods

Subjects: Eleven hospitalized patients with CHF diagnosed on the basis of dyspnea, cardiomegaly, basilar rales, elevated jugular venous pressure, and signs of pulmonary hypertension were studied. Their age and sex, the cause and severity of congestive heart failure, and drugs concomitantly given are shown in Table I. Digitalis, diuretics, and nitroglycerin ointment were withheld 6 hours before each study. Various catecholamines were administered at the same doses throughout the studies.

Methods: In all patients, right pulmonary arterial and right atrial pressures were continuously monitored through a Swan-Ganz balloon-tipped triple-lumen catheter (Edwards Laboratories), 746 Simens pressure transducers, and Simens Mingograf 34. Cardiac output was measured by thermodilution techniques with the use of ice-cold water. Computation of cardiac output was performed by a bedside computer (model 9520 cardiac output computer, Edwards Laboratories). Mean arterial blood pressure (MBP) was estimated from the following formula: MBP = diastolic pressure + (systolic pressure − diastolic pressure)/3. Pulmonary arterial end-diastolic pressure was used to determine left ventricular filling pressure. The following parameters of cardiac performance were calculated: cardiac index = cardiac output/body surface

TABLE I Subjects

Case	Age (yr) & Sex	Diagnosis	Forrester's Hemodynamic Subset	Combined Drugs
1	68F	SH	. . .	None
2	57M	DC	. . .	Digitalis, diuretics

10	69M	AMI	H-IV	Dopamine, dobutamine
11	68M	AMI	H-IV	NTG ointment, dopamine, dobutamine

AMI = acute myocardial infarction; DC = dilated cardiomyopathy; IAPB = intraaortic balloon pumping; MR = mitral regurgitation; NTG = nitroglycerin; RV = right ventricular; SH = systemic hypertension.

area (BSA) (liters/min/m^2); stroke volume index = cardiac index/heart rate (beats/min) × 1,000 (ml/beat/m^2); left ventricular stroke work index = (MBP − pulmonary arterial end-diastolic pressure) × stroke volume index × 0.0136 (g − m/m^2); total systemic vascular resistance index = (MBP − mean right atrial pressure)/cardiac index × 80 (dynes s $cm^{-5}{\cdot}m^2$); pulmonary vascular resistance index = (mPA − pulmonary arterial end-diastolic pressure)/cardiac index × 80 (dynes s $cm^{-5}{\cdot}m^2$), where mPA is mean pulmonary arterial blood pressure; and double product = arterial systolic blood pressure × heart rate.

The doses of DBcAMP and the time at which hemodynamic measurements were taken in each patient are shown in Figure 1. In cases 1 to 6, DBcAMP was infused continuously at rates of 0.05, 0.1, and 0.2 mg/kg/min. Each infusion rate was maintained for 20 minutes. Hemodynamic measurements were performed before and 20, 40, and 60 minutes after the start of the infusion and 30 and 60 minutes after terminating the infusion. In case 7, DBcAMP was infused at a rate of 0.2 mg/kg/min for 30 minutes. Hemodynamic measurements were repeated before and 10, 20, and 30 minutes after the start of the infusion, and 30 minutes after terminating the infusion. In case 8, DBcAMP was infused at a rate of 0.2 mg/kg/min for 20 minutes. Hemodynamic variables were measured before and 10 and 20 minutes after the start of the infusion, and 30 and 60 minutes after terminating the infusion. In case 9, DBcAMP was administered continuously at a rate of 0.05 mg/kg/min for 20 minutes and at a rate of 0.1 mg/kg/min for about 6 hours thereafter. Hemodynamic variables were measured before and 20 and 40 minutes after the start of the infusion. In case 10, DBcAMP was infused continuously at a rate of 0.05 mg/kg/min for the first 2 hours and 0.1 mg/kg/min for about 9 hours. Hemodynamic variables were measured before and 2, 4.5, and 10 hours after the start of the infusion. In case 11, DBcAMP was infused at a rate of 0.025 mg/kg/min for the first 30 minutes and at a rate of 0.05 mg/kg/min for about 100 minutes thereafter. Hemodynamic variables were measured before and 30 minutes after the start of the infusion. The data obtained were analyzed by Student's t test and a difference was regarded as significant at $p < 0.05$.

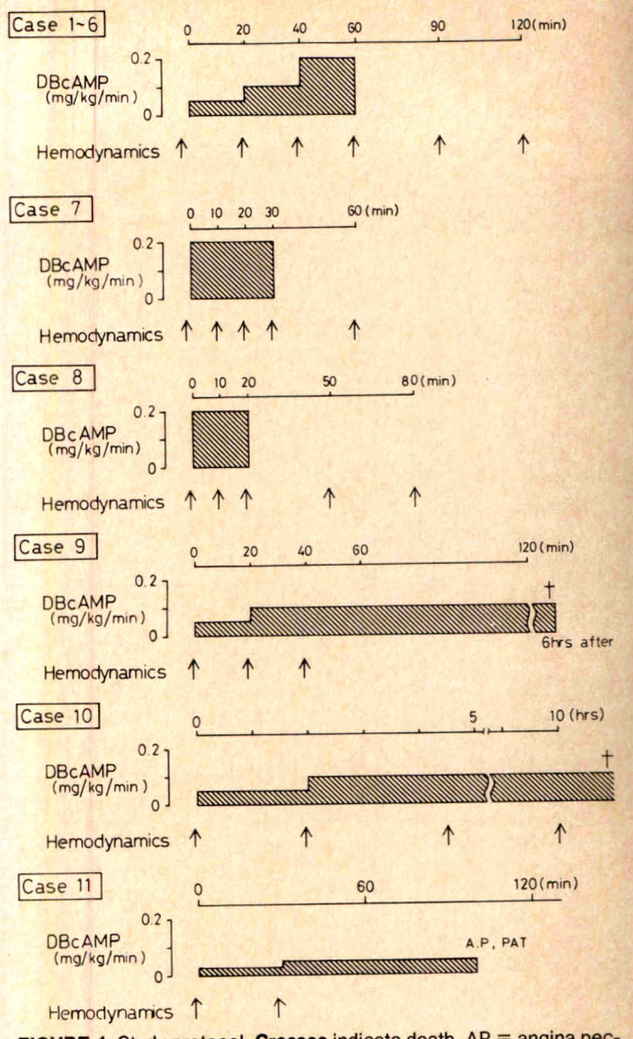

FIGURE 1. Study protocol. **Crosses** indicate death. AP = angina pectoris; PAT = paroxysmal atrial tachycardia.

Results

Hemodynamic response after intravenous administration of DBcAMP: Figure 2 shows the time course of changes of various hemodynamic variables in the patient who received continuous infusion of DBcAMP at a rate of 0.2 mg/kg/min for 30 minutes. Total systemic vascular resistance index and arterial blood pressure showed an initial decrease, whereas cardiac index showed an increase by 20 minutes and these reached constant values 20 minutes after the start of the infusion, whereas pulmonary arterial end-diastolic pressure kept declining from the beginning of the infusion to the end.

The maximal doses of DBcAMP varied from 0.025 to 0.2 mg/kg/min and averaged 0.14 ± 0.077 mg/kg/min (mean ± standard deviation). Mean arterial blood pressure, pulmonary arterial end-diastolic pressure, and total systemic vascular resistance index were significantly decreased and heart rate, cardiac index, and stroke volume index were significantly increased. However, there were no significant changes in mean

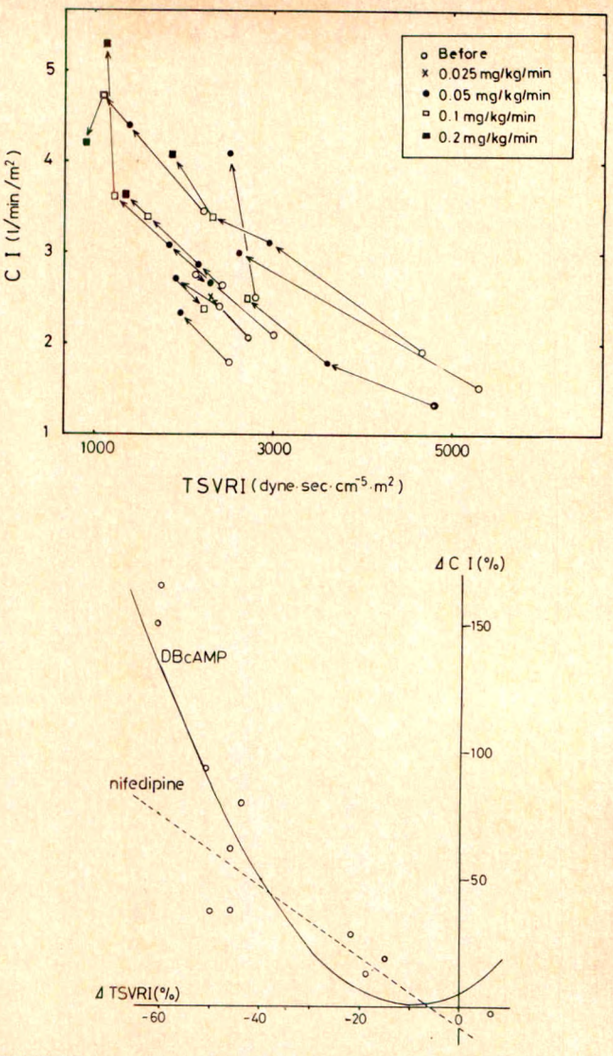

FIGURE 3. Top, effect of DBcAMP on the relation between cardiac index (CI) and total systemic vascular resistance index (TSVRI) in patients with CHF. **Bottom,** regression lines for DBcAMP and nifedipine for the percent change in cardiac index versus the percent change in the total systemic vascular resistance index. R for DBcAMP (**solid line**) = 0.90 ($p < 0.01$), R for nifedipine (**dotted line**) = 0.94 ($p < 0.01$).[14]

right atrial pressure, pulmonary vascular resistance index, and double product.

Figure 3, left, shows the change in cardiac index as a function of the changes in total systemic vascular resistance index. The increase in cardiac index was accompanied by a proportional decrease in the total systemic vascular resistance index in all patients but 1, and in 2 of them the decrease in cardiac index was accompanied by an increase or decrease in the total systemic vascular resistance index after infusing the incremental doses of DBcAMP. The relation of both parameters was regressed to a secondary degree curve with a correlation coefficient of 0.90 when their changes (cardiac index and total systemic vascular resistance index) were expressed in percentages. Compared with nifedipine,[14] DBcAMP produced larger changes in the cardiac index in patients who showed a reduction in the total systemic vascular resistance index by ≥40% (Fig. 3, right).

Individual changes in left ventricular stroke work index and pulmonary arterial end-diastolic pressure are illustrated in Figure 4. In 8 patients, the decrease in pulmonary arterial end-diastolic pressure was accompanied by an increase or no change in left ventricular stroke work index. In 2 of the other 3 patients, left ventricular stroke work index decreased together with an increase or no change in pulmonary arterial end-diastolic pressure.

In the relation between cardiac index and pulmonary arterial end-diastolic pressure, cardiac index increased along with a decrease in pulmonary arterial end-diastolic pressure in 8 of 11 patients (Fig. 5).

Dose-response relation and duration of effects: In 6 patients (cases 1 to 6), DBcAMP was given in incremental doses of 0.05, 0.1, and 0.2 mg/kg/min every 20 minutes, and 5 of 6 patients (cases 1 to 5) tolerated the full dose. DBcAMP produced a dose-related hemodynamic effect, increasing cardiac index and decreasing mean arterial blood pressure, pulmonary arterial end-diastolic pressure, and total systemic vascular resistance index. These effects of DBcAMP lasted at least 1 hour after termination of the infusion (Fig. 6).

Side effects: In case 5, arterial blood pressure decreased significantly at an infusion rate of 0.2 mg/kg/min. In case 6, premature ventricular contractions increased at an infusion rate of 0.2 mg/kg/min. In case 11, anterior chest pain and supraventricular tachycardia were noted at an infusion rate of 0.05 mg/kg/min.

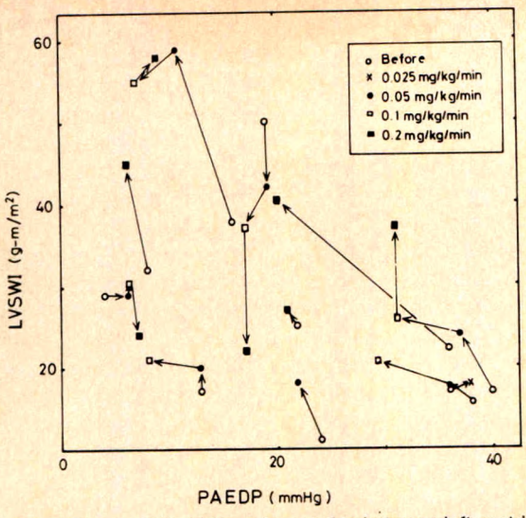

FIGURE 4. Effect of DBcAMP on the relation between left ventricular stroke work index (LVSWI) and pulmonary arterial end-diastolic pressure (PAEDP) in patients with CHF.

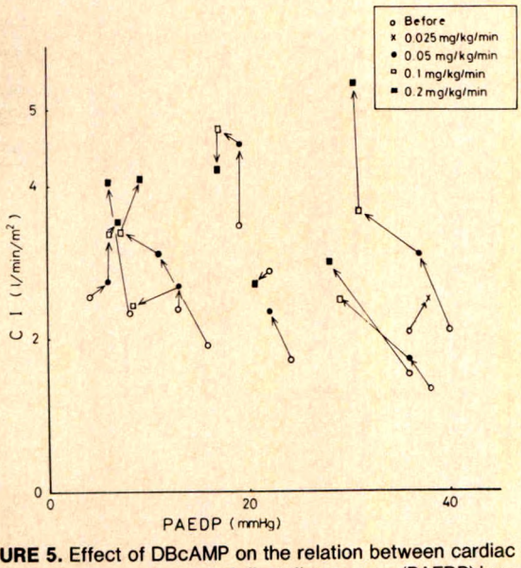

FIGURE 5. Effect of DBcAMP on the relation between cardiac index (CI) and pulmonary arterial end-diastolic pressure (PAEDP) in patients with CHF.

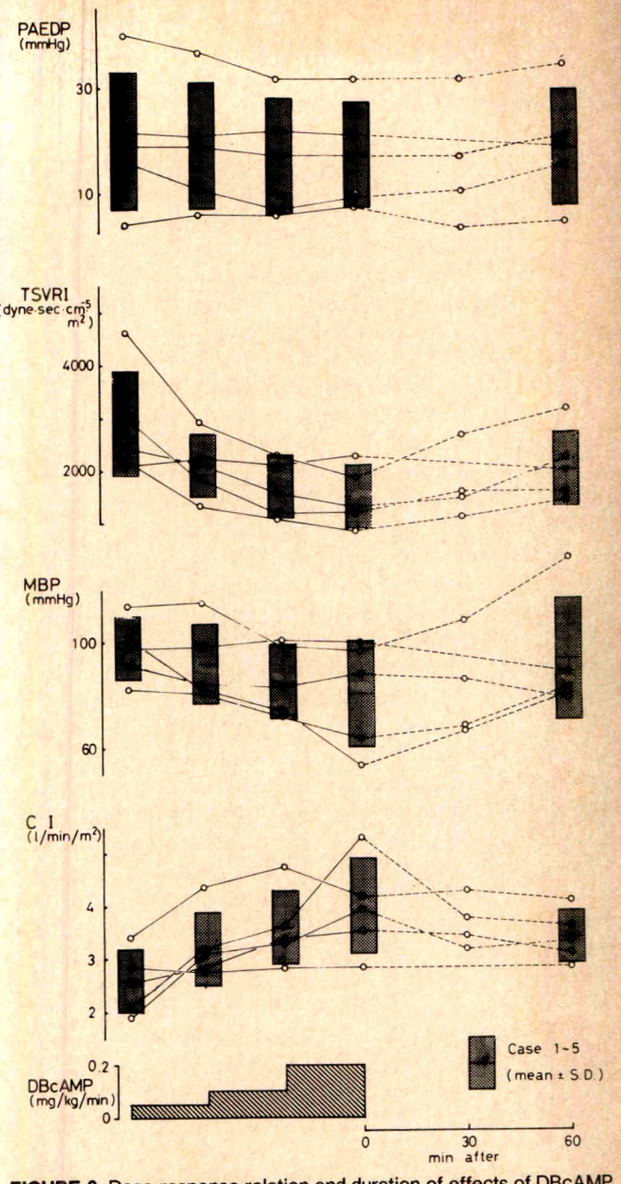

FIGURE 6. Dose-response relation and duration of effects of DBcAMP in patients with CHF (cases 1 to 5). CI = cardiac index; MBP = mean arterial blood pressure; PAEDP = pulmonary arterial end-diastolic pressure; TSVRI = total systemic vascular resistance index.

Discussion

Robinson et al[5] published the first report concerning the effects of DBcAMP on cardiac function in 1965. They reported that concentrations of DBcAMP as high as 6 by 10^{-4} *M* produced no effect on the performance of the isolated perfused rat heart. Posternak et al,[6] in anesthetized dogs, found that the intravenous injection of DBcAMP in a dose of 4 mg/kg caused only minimal and variable changes in the cardiovascular performance. However, in 1970 Kukovetz and Poch[7] reported that the addition of DBcAMP to Langendorff preparations of heart from rats, rabbits, and guinea pigs increased both their myocardial contractility and their phosphorylase activity. After this report, Skelton et al,[8] Iwatsuki and Iwatsuki,[10] and Imai et al[11] demonstrated successively that DBcAMP increased both myocardial contractility and heart rate. Nozaki and Okuaki[13] reported that the administration of DBcAMP at a dose of 5 mg/kg increased cardiac output and renal blood flow and decreased mean arterial blood pressure and total peripheral vascular resistance in anesthetized dogs. The explanation for these differences in cardiac response by DBcAMP between studies is not yet clear, but they may be related to species differences as well as to differences in dose. Thus, optimal doses of DBcAMP may have positive inotropic and chronotropic effects on the heart and vasodilating effects in the peripheral vessels. Moreover, previous studies have indicated that the positive inotropic effect of DBcAMP is not suppressed by beta-receptor blocking agents and DBcAMP may have a direct dilating effect on coronary arteries.[8,9,11,13]

A few clinical reports have described the hemodynamic effects of DBcAMP during cardiac catheterization or after extracorporeal circulation.[15–18] In these reports (in which the dose of DBcAMP was 0.2 mg/kg/min or a single injection of 5 mg/kg), a marked increase in cardiac output, a decrease in peripheral vascular resistance, and a slight increase in heart rate were observed. However, some investigators have reported that DBcAMP showed no positive inotropic effect.[18]

These results in experimental animals and the clinical studies suggest that DBcAMP may be useful in the management of CHF. However, there have been no reports concerning the effects of DBcAMP on CHF. In the present study the administration of DBcAMP at a rate of 0.025 to 0.2 mg/kg/min markedly decreased total peripheral vascular resistance and increased cardiac output in patients with CHF. Heart rate was increased slightly, arterial blood pressure was decreased, and pulmonary arterial end-diastolic pressure, indicative of left ventricular filling pressure, was decreased slightly. The double product, indicative of myocardial oxygen consumption, was not changed significantly. These results suggest that DBcAMP may be useful as a therapeutic agent for CHF.

There was no direct relation between pulmonary arterial end-diastolic pressure and cardiac index after administration of DBcAMP, as would be predicted by a simple Starling mechanism with fixed impedance and myocardial contractility. The change in cardiac output was proportional to the decrease in systemic vascular resistance by the administration of DBcAMP. Thus, the effect of DBcAMP on cardiac output is thought to be mediated in large part by a change in systemic vascular resistance. However, when a decrease in the total systemic vascular resistance index expressed as a percent of the control was reduced by more than 40%, an increase in cardiac index by DBcAMP was more than that by nifedipine, a calcium antagonist with a strong dilating effect on the resistance vessels.[14] Therefore, DBcAMP was thought to have a slight positive inotropic effect at an infusion rate of 0.025 to 0.2 mg/kg/min. Unchanged mean right atrial pressure suggests that DBcAMP has no effect on the venous bed, so that the reduction in left ventricular filling pressure is presumably due to improvement in the left ventricular pump function.

In most patients an increase in cardiac index and left ventricular stroke work index was accompanied by a decrease in left ventricular filling pressure. These results suggest that DBcAMP improved left ventricular function in patients with CHF. However, as in 2 patients, the left ventricular function was deteriorated by DBcAMP, careful hemodynamic monitoring should be performed during intravenous administration of this drug.

The maximal effect of DBcAMP on cardiac index and total systemic vascular resistance index appeared 20 minutes after initiation of the infusion and the effect lasted for at least 1 hour after termination of the infusion. The effect of DBcAMP was dose-dependent at an infusion rate from 0.05 to 0.2 mg/kg/min. However, DBcAMP at a dose of 0.2 mg/kg/min caused marked hypotension in case 5 and increased premature ventricular contractions in case 6. From these results, the most effective dose range of DBcAMP in patients with CHF appeared to be 0.05 to 0.1 mg/kg/min, but in case 11 chest pain and supraventricular tachycardia were observed at a rate of 0.05 mg/kg/min. Therefore, the administration of DBcAMP should be commenced with a smaller dose and increased gradually under careful hemodynamic monitorings.

Because DBcAMP has a powerful vasodilating effect on resistance vessels in the dose range used here, it is expected to be useful for vasodilator therapy of CHF. Moreover, DBcAMP was thought to have a slight positive inotropic effect in patients with CHF. Thus, these hemodynamic effects of DBcAMP support the clinical usefulness of this drug in the management of patients with CHF.

Pharmacokinetic and Pharmacodynamic Effects of Diltiazem

MARK S. SMITH, MD, CHACKO P. VERGHESE, MS,
DAVID G. SHAND, MB, PhD, and EDWARD L. C. PRITCHETT, MD

The pharmacokinetic and pharmacodynamic effects of diltiazem were studied in 8 patients after a short intravenous infusion (20 mg over 10 minutes), a single oral dose (60 or 90 mg), and repeated oral administration (60 or 90 mg every 6 hours for 16 doses). Diltiazem levels decreased in a triexponential manner after intravenous infusion. Terminal half-lives after intravenous, single oral, and repeated oral administration were not significantly different (4.5 ± 1.3, 3.7 ± 0.6, and 4.9 ± 0.4 hours, respectively). The kinetic effects of oral diltiazem were nonlinear. With repeated oral administration, there was accumulation of both diltiazem and its metabolite, deacetyldiltiazem. The diltiazem area under the time versus concentration curve increased by a factor of 2.39 ± 0.42 ($p = 0.00002$). Most patients showed a double peaked time versus concentration curve after oral administration, indicating possible enterohepatic recirculation.

After intravenous administration, there was a substantial increase in the P-R interval (14.3 ± 5.4%). Although only small changes in P-R interval were seen with a single oral dose, with chronic administration there was persistent P-R interval prolongation, peaking at 17.3 ± 5.6% over control. Counterclockwise hysteresis was present in the P-R interval versus plasma diltiazem concentration curve after intravenous administration. Only small changes were seen in heart rate and blood pressure.

Diltiazem hydrochloride (d-cis-3-acetoxy-2,3-dihydro-5-[2-(dimethyl-amino)-ethyl]-2-(p-methoxyphenyl)-1,5-benzothiazepin-4(5H)-one hydrochloride) is a new benzothiazepine derivative with cardiac and smooth muscle calcium-channel blocking activity. It is a potent vasodilator useful in the treatment of angina pectoris (due to coronary artery spasm or atherosclerosis), systemic hypertension, pulmonary hypertension, and hypertrophic cardiomyopathies.[1–5] Limited information is available about the clinical pharmacologic effects of diltiazem because the assay procedure for plasma drug levels has been cumbersome and not widely available. In this report we describe the detailed pharmacokinetic effects of oral and intravenous diltiazem measured using a new sensitive and specific high performance liquid chromatographic assay. In addition, we describe the pharmacodynamic aspects of P-R interval prolongation with diltiazem, which is a measure of its negative dromotropic effect.

Methods

Eight patients with a history of paroxysmal atrial tachycardia (3 women and 5 men, aged 22 to 58 years) were admitted to the Duke University Clinical Research Unit. One patient had a delta wave on the electrocardiogram recorded during sinus rhythm (Wolff-Parkinson-White syndrome). Three patients had coexisting diseases: 1 each with chemical diabetes, chronic obstructive pulmonary disease, and type IV hyperlipidemia. All medications were discontinued at least 5 half-lives before admission, except in 1 patient who required continuous theophylline therapy.

All studies were performed while patients were in normal sinus rhythm. Patients were given nothing by mouth and were kept at complete bed rest from midnight forward on each study day. Between 7 and 8 A.M. a Teflon® catheter (Quick Cath 2N114, Travenol Laboratories) was inserted into a superficial forearm vein and capped with a sterile obturator (Quick Cath 2N1152, Travenol Laboratories). The catheters were kept open by the sterile obturators and heparin was not used. On days when intravenous studies were performed, a second Teflon catheter was inserted into the opposite arm and connected to a continuous infusion of 5% dextrose solution. An electrocardiographic telemetry transmitter (Hewlett-Packard model 78100A and 78101A) was used to record a

* Patient 5 received 17 mg and all dose-dependent variables were extrapolated to 20 mg.

A, B, and G are the time-zero intercepts and α, β, and γ the rate constants for the triexponential equation $Ct = Ae^{-\alpha t} + Be^{-\beta t} + Ge^{-\gamma t}$ used to describe the decrease in plasma concentration after intravenous injection. Ct is the concentration of drug at time = t. $t^{1}/_{2}\alpha$, $t^{1}/_{2}\beta$, and $t^{1}/_{2}\gamma$ are the half-lives for the α, β, and γ phases of drug elimination. AUC is area under the plasma concentration versus time curve. Vc is the volume of the central compartment calculated using the equation: Vc = dose/(A + B + G). Vd area is the volume of distribution calculated using the equation: Vd_{area} = dose/(AUC × γ). Vd_{ss} is volume of distribution at steady-state. C_{max} is the maximum plasma level of diltiazem after the intravenous infusion.

modified electrocardiographic lead II (right shoulder negative, cardiac apex positive). The electrocardiogram was displayed continuously on an oscilloscope and recorded on an Elema Mingograph model 1600 ink-jet recorder. Between 8 and 9 A.M., electrocardiogram rhythm strips that included at least 10 consecutive sinus beats were recorded at a paper speed of 100 mm/s, and blood pressure was measured by a sphygmomanometer at 15-minute intervals. At exactly 9 A.M. the medication was given. For intravenous administration, 20 mg of diltiazem (Cardizem, Marion Laboratories) in a solution of 1 mg/ml of sterile water was given over 10 minutes by constant infusion pump (Harvard Apparatus infusion withdrawal pump). Blood samples were obtained before the infusion began and at t = 0, 2, 3, 5, 7, 10, 15, 30, 45, and 60 minutes and 2, 3, 4, 5, 6, 8, 10, 12, 24, and 48 hours after completion of the infusion. Blood pressure was measured and electrocardiogram rhythm strips were recorded at the time each blood sample was drawn.

Two days after the intravenous infusion study, a single oral dose of diltiazem was given (60 or 90 mg as two or three 30 mg tablets of the Tanabe formulation). Blood samples were obtained, electrocardiographic rhythm strips were recorded, and blood pressure was measured immediately before the tablets were given and at t = 0, 0.5, 1, 1.5, 2, 2.5, 3, 3.5, 4, 4.5, 5, 5.5, 6, 6.5, 7, 8, 9, 10, 11, and 12 hours after the dose was given. After the 12-hour sample was obtained, patients were given oral diltiazem every 6 hours, continuing the dose they received for the initial oral study (60 mg for the first 4 patients and 90 mg for the last 4 patients). Blood samples were obtained each morning at 9 A.M. to determine trough plasma diltiazem levels. Four days after the single-dose study, a repeat pharmacokinetic study was done over the same 12-hour period to assess steady-state pharmacokinetic effects after the 16th dose.

Blood samples were drawn into plastic syringes and immediately transferred to silanized glass tubes with 10 U/ml of heparin. Plasma was separated and frozen at −20°C and later analyzed for diltiazem and deacetyldiltiazem using a high performance liquid chromatographic method described by Verghese et al.[6] The mean P-R interval and cardiac cycle on 10 consecutive heart beats recorded at the specified sampling times were measured using an interactive computer program, except for the patient with the Wolff-Parkinson-White syndrome who was excluded from analysis of electrocardiographic data. Electrocardiograms were measured and blood samples assayed blindly by personnel in separate laboratories.

Initial estimates of the intravenous parameters were obtained using linear regression of time versus log of concentration plots. These estimates were refined by nonlinear regression analysis for both a 2 and a 3 exponential model. Half-lives ($t^{1}/_{2}$) for the oral studies were determined using linear regression of the terminal portion of the time versus concentration curves. The area under the time versus concentration curve (AUC) was estimated by the trapezoid rule. The accumulation factor (A) was calculated using the following equation: $A = AUC_{16}0 \rightarrow 6/AUC_{1}0 \rightarrow \infty$ where $AUC_{16}0 \rightarrow 6$ is the AUC after the 16th oral dose from 0 to 6 hours, and $AUC_{1}O \rightarrow \infty$ is the AUC after the first oral dose extrapolated to infinity. The apparent bioavailability (F), was calculated using the equation: $F = (AUC_{oral}/AUC_{iv}) \times (D_{iv}/D_{oral})$, where D_{iv} is the intravenous dose and D_{oral} the oral dose given. Volume of distribution at steady state (Vd_{ss}) was calculated using the equation: $Vd_{ss} = [(A/\alpha^2 + B/\beta^2 + G/\gamma^2)/(AUC_{iv}0 \rightarrow \infty)] \times$ clearance. The half-lives of the intravenous, the first oral, and the steady-state oral studies were compared using the analysis of variance. Other comparisons were analyzed using the paired *t* test.

Patient 5 received only 17 mg during the intravenous study because the infusion rate was inappropriately slow. Plasma

levels and all dose-dependent parameters were extrapolated to a dose of 20 mg in this patient.

Results

Pharmacokinetic effects: Immediately after the short intravenous infusion plasma levels peaked at 312 ± 93 ng/ml and thereafter decreased triexponentially (Table I, Fig. 1). The mean terminal half-life was 4.5 ± 1.3 hours. Plasma diltiazem was not detectable after 24 hours except in 2 patients, and they had only a trace amount. Deacetyldiltiazem was measured in all 8 patients at t = 0 after the infusion (peak plasma level 41.1 ± 19 ng/ml), but plasma levels of the metabolite were not adequate to determine its kinetic effects.

There was substantial overlap in the results obtained with the 60 and 90 mg single oral doses; combined results are presented in Table II. In 6 of 8 patients we found 2 distinct plasma diltiazem peaks, 63.0 ± 34 ng/ml at 1.8 ± 0.5 hours and 64.7 ± 39 ng/ml at 4.7 ± 0.7 hours (Fig. 2). The peak plasma diltiazem levels in the remaining 2 patients were 92 ng/ml at 4.5 hours and 61 ng/ml at 4.5 hours. The mean terminal half-life after the later peak was 3.7 ± 0.6 hours, not significantly different from that found after intravenous administration (described earlier) or after steady-state oral dosing (described later).

Deacetyldiltiazem was not detected in 1 patient receiving a 60 mg dose and in 1 patient receiving a 90 mg dose. In the other 6 patients, peak levels ranged from 6 to 27 ng/ml (20 ± 7.7). As after intravenous diltiazem, deacetyldiltiazem levels after a single oral dose were not high enough to determine its kinetics. In addition, there was considerable fluctuation in the metabolite level from hour to hour, making it impossible to measure rate constants.

During chronic administration, trough plasma levels increased initially and then stabilized after 48 hours (7 doses), indicating that steady-state plasma drug levels had been achieved. After the 16th dose, 4 patients continued to have 2 diltiazem peaks in plasma: 205 ± 80 ng/ml at 1.6 ± 0.6 hours and 192.5 ± 79 ng/ml at 4.0 ± 1.0 hours. The 4 patients with single peaks achieved levels of 144 ng/ml at 1.5 hours, 473 ng/ml at 2.0 hours, 277 ng/ml at 2.5 hours, and 361 ng/ml at 4.5 hours. The mean terminal half-life of diltiazem was 4.9 ± 0.4 hours at steady-state.

The mean peak plasma deacetyldiltiazem level after the 16th dose was 93 ± 76 ng/ml. In 6 patients, the deacetyldiltiazem level peaked 1 to 5 hours after dosing (Fig. 3A). The terminal half-life was 6.1 ± 1.2 hours in 5 patients for whom this calculation could be made. In 2 patients, the plasma deacetyldiltiazem level showed no decrease during the 12-hour study interval, and levels were higher than diltiazem in 1 patient (Fig. 3B). This latter patient required continuous theophylline therapy throughout the study, and the relation to deacetyldiltiazem levels is not clear.

When steady-state was achieved, the AUC had significantly increased from 505 ± 205 ng/ml × hour after the initial dose to 1,216 ± 562 ng/ml × hour (p = 0.0008). The mean accumulation ratio was 2.39 ± 0.42. In addition, the apparent bioavailability increased from 38 ± 11% to 90 ± 21% (p = 0.00002). In 3 patients the apparent bioavailability was >100% after the 16th dose.

Pharmacodynamic effects: The mean P-R intervals recorded during control periods were 161 ± 11 ms on the intravenous dosing day and 159 ± 12 ms on the first oral dosing day (p = 0.4). After intravenous diltiazem, the P-R interval increased by 14.3 ± 5.4%. Peak prolongation occurred 11.4 ± 2.4 minutes after the infusion

stopped and thus lagged behind the peak plasma diltiazem level. This lag caused counterclockwise hysteresis in the curve of P-R interval prolongation versus plasma diltiazem concentration (Fig. 4). After the first oral dose, P-R interval prolongation was only 6.0 ± 1.5% for 4 patients receiving 60 mg and 8.0 ± 3.6% for patients receiving 90 mg. These changes were too small to determine whether hysteresis was present.

When diltiazem was given to steady-state, P-R interval prolongation persisted throughout the dosing interval. The P-R interval at the time the 16th dose was given was 176 ± 17.6 ms or 10.6% greater than that recorded during the control period of the first oral dosing day ($p = 0.002$). The peak P-R interval after the 16th dose was 187.4 ± 16.7 ms or 17.3% greater than that recorded during the control period of the first oral dosing day, and occurred 1.5 ± 0.05 hours after the dose. Six hours after the 16th dose, the P-R interval was still significantly prolonged at 171.3 ± 13.5 ms ($p = 0.003$).

There was no clinically important change in heart rate recorded on any study day. On the intravenous dosing day, the mean heart rate was 66.6 ± 15 beats/min during the control period and 71.5 ± 13 beats/min at the end of infusion. Blood pressure decrease was modest during intravenous dosing. In most patients the maximum decrease in blood pressure occurred at the end of the intravenous infusion. The average decrease was 6.3 mm Hg in systolic and 4.0 mm Hg in diastolic blood pressure between control values and values immediately after infusion. Changes in blood pressure were even less in the oral dosing studies.

No significant adverse effects occurred which could be attributed to diltiazem. No patient had clinically important hypotension, or changes in blood counts, renal function, electrolytes, or liver function test results.

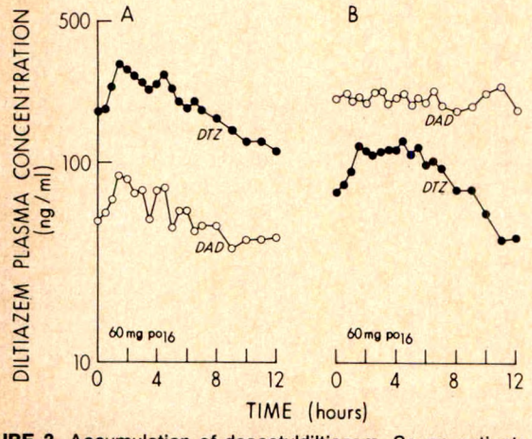

FIGURE 3. Accumulation of deacetyldiltiazem. Seven patients had plasma deacetyldiltiazem (DAD) levels lower than plasma diltiazem (DTZ) levels at steady-state (**A**). In 1 patient, plasma deacetyldiltiazem levels exceeded those of the parent compound (**B**).

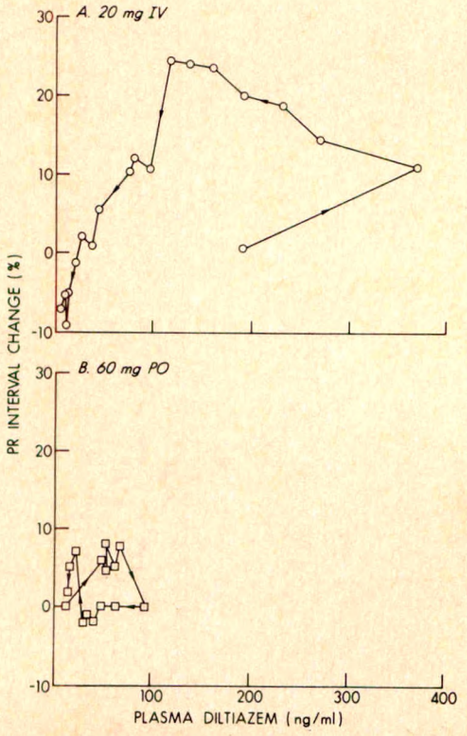

FIGURE 4. Percent change in P-R interval from control versus plasma diltiazem concentration after intravenous (IV) (**A**) and oral (PO) (**B**) diltiazem. Counterclockwise hysteresis was present after intravenous administration.

Discussion

Diltiazem is a new calcium-channel blocking drug that probably will soon be widely used for the treatment of angina. Important new findings in our study are (1) nonlinear kinetic effects leading to a significant accumulation with chronic oral dosing, (2) substantial levels of deacetyldiltiazem (exceeding those of the parent compound in some patients) that might contribute to therapeutic or toxic effects, (3) double peak in plasma drug concentration versus time curve consistent with enterohepatic recirculation, (4) sustained atrioventricular nodal slowing measured as P-R interval prolongation with chronic dosing, (5) terminal half-life 4.5 hours and triexponential elimination after intravenous administration, and (6) counterclockwise hysteresis in P-R interval versus plasma drug concentration curves after rapid infusion.

Oyama et al[7] previously reported a half-life of 2 hours for intravenous diltiazem, which is substantially shorter than our value of 4.5 hours. This discrepancy may be explained because Oyama et al used a 2-compartment model to describe their data. In the present study, diltiazem elimination was clearly triexponential in all patients. Our values for the half-life after first oral and steady-state oral dosing (3.7 and 4.9 hours, respectively) are more consistent with those previously reported for single oral doses.[8–10] In contrast to verapamil, which has a half-life that increases with chronic oral dosing, we found that diltiazem's half-life was not affected by route of administration or length of treatment.[11] Like those of verapamil, our pharmacokinetic data are consistent with high "first-pass elimination" in the liver with nonlinear kinetic effects that cause unexpected drug accumulation during chronic administration. Therefore, bioavailability was low with the first oral dose (38%) but high (90%) with steady-state oral dosing. This finding differs from the findings of Rovei et al,[8] who reported only slight accumulation, and Morselli et al[9] who reported plasma drug level actually decreasing over time in some patients. The reason for this discrepancy is not obvious since we saw ≥100% increase in the AUC (or ≥50% reduction in clearance) in each patient studied. The importance of this finding is clear: like verapamil and propranolol, diltiazem given on a long-term basis leads to unexpected accumulation.[11,12] This now appears to be the rule rather than the exception for drugs with high first-pass metabolism; this is presumably due to saturation of the elimination pathway for diltiazem. This mechanism is also suggested by previous work showing a nonlinear increase in AUC with increasing dose and higher bioavailability with larger doses.[10,13] The increase we found in apparent bioavailability with time also suggests saturation.

The double peak in plasma concentration-time curves after oral administration is a new and unusual finding, but not entirely unexpected. While diltiazem is rapidly and almost completely absorbed, its main route of excretion is in the feces.[14] Using radiolabeled diltiazem, Sakuma et al[15] showed excretion into the stomach from fundic glands and into the small intestines from the bile ducts. Meshi et al[14] also showed enterohepatic recirculation using a cross-cannulation experiment in rats. Piepho et al[13] reported that 3 of 6 dogs given oral diltiazem also had secondary peaks. While this could be explained by conversion of deacetyldiltiazem back to diltiazem or the presence of an immediate and delayed release of diltiazem from the tablets, recirculation seems more likely. The finding of >100% bioavailability in 3 patients is probably due to a combination of a small amount of enterohepatic recirculation amplified by a reduction in clearance with long-term therapy.

The metabolite deacetyldiltiazem also accumulated with time in all patients, and had an elimination half-life considerably longer than its parent compound. We also found that the plasma level of the metabolite exceeded the level of diltiazem during long-term therapy in some patients. A considerably longer period of time may be required to reach steady-state levels of deacetyldiltiazem. Potential therapeutic benefits or toxic effects of deacetyldiltiazem are not known.

Although diltiazem is being introduced as an antianginal agent, it also slows atrioventricular nodal conduction (negative dromotropic effect) like verapamil. The 14% P-R interval prolongation that we found with our short infusion (20 mg over 10 minutes) is less than the 25% prolongation reported with intravenous verapamil (10 mg over 2 minutes) by Reiter et al.[16] As with verapamil, peak P-R interval prolongation occurred 11 minutes after peak plasma drug levels, causing counterclockwise hysteresis (Fig. 4), which has been reported previously only for verapamil among the calcium-channel blocking drugs.[17–19] This phenomenon is probably due to a delay in the transfer of diltiazem from the plasma to the tissue compartment, estimated by Kohno et al[20] to take 11 minutes in dogs. Counterclockwise hysteresis was also found after single oral dosing with verapamil, but with diltiazem, P-R interval prolongation and plasma levels were insufficient to assess hysteresis after a single oral dose. However, with long-term administration, as diltiazem accumulated, the P-R interval was significantly prolonged. This suggests that diltiazem will be useful in the chronic management of supraventricular tachycardias.

Diltiazem users should be aware of its unique pharmacokinetic properties. Significant accumulation occurs when the drug is given orally, which may enhance its therapeutic benefits or may possibly increase toxicity. The role of deacetyldiltiazem in the efficacy of diltiazem is uncertain, but it is present in substantial quantities. In addition, the negative dromotropic effect of both intravenous and oral diltiazem suggests that it may be useful in the treatment of supraventricular tachycardias.

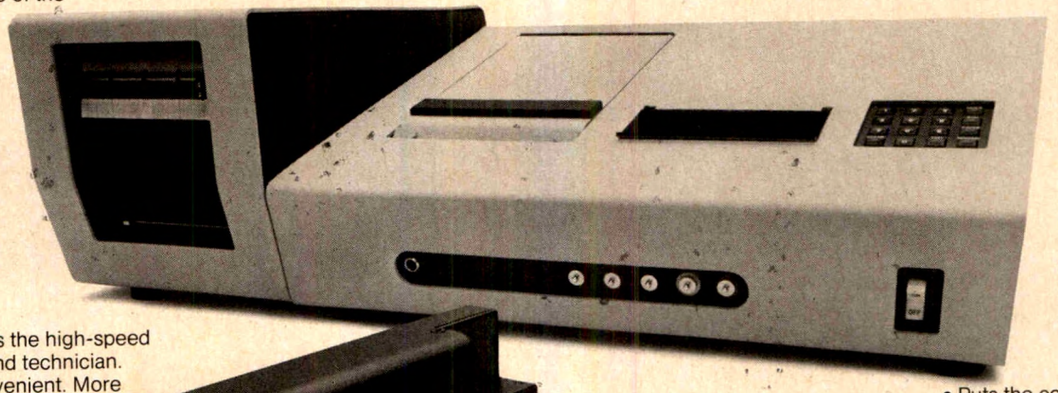
Clinical evaluation of various systems for analysis of ambulatory ECG records has been difficult to implement due to the variety of approaches to recording data, the operator-dependence of traditional recording and interpretation systems, and the subjective clinical judgements necessary in using the final results. One manufacturer can now report data utilizing a real-time approach to ambulatory monitoring that compares clinical accuracy to hand-counted data as a standard.[1]

In Holter studies, AEGIS™ gives you results in minutes... right in your office... without a specially trained operator.

rovides the same clinical ormation as a scanning rvice—with none of the awbacks.

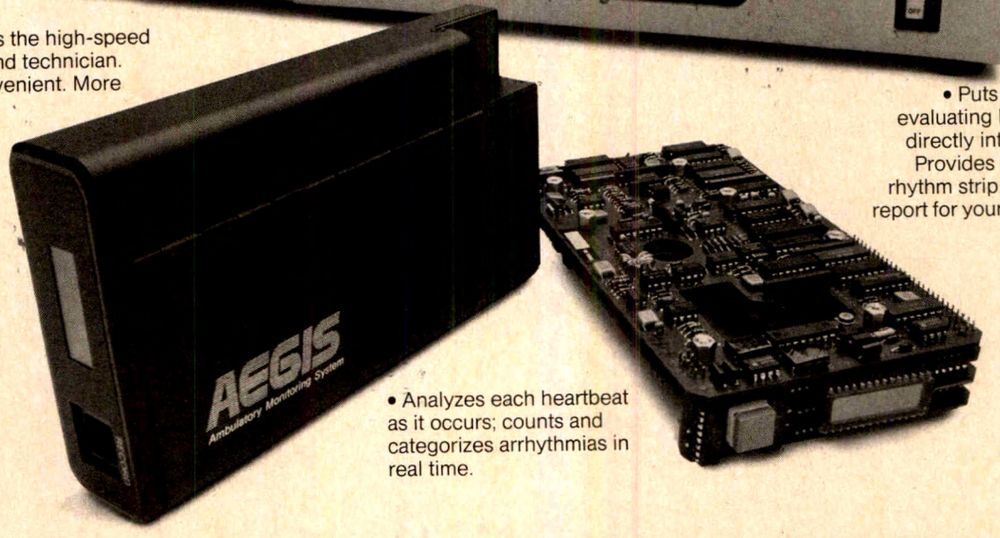
• Fits easily into any office.

• System validates itself—no need for repeat studies due to "lost" data or faulty equipment.



• Replaces the high-speed scanner and technician. More convenient. More efficient.

• Puts the control of evaluating Holter studies directly into your hands. Provides time-stamped rhythm strip and summary report for your confirmation.



• Analyzes each heartbeat as it occurs; counts and categorizes arrhythmias in real time.

For a 15-minute, no obligation demonstration, call toll-free: 800-257-5750.

Prevalence of Submitral (Anular) Calcium and Its Correlates in a General Population-Based Sample (The Framingham Study)

DANIEL D. SAVAGE, MD, PhD, ROBERT J. GARRISON, MS, WILLIAM P. CASTELLI, MD, PATRICIA M. McNAMARA, BA, SANDRA J. ANDERSON, BS, RN, WILLIAM B. KANNEL, MD, MPH, and MANNING FEINLEIB, MD, Dr PH

To obtain epidemiologic information on submitral calcium, 2,069 subjects in the original Framingham Study cohort (mean age 70 ± 7 years) and 3,625 of the offspring of the cohort and their spouses (mean age 44 ± 10 years) with adequate echocardiograms were evaluated. Submitral calcium was detected in 162 (2.8%) of the 5,694 subjects; >90% of the subjects with such calcium came from the 40% of the study group >59 years of age. Women were more than twice as likely to have such calcium as men. Age in both sexes, systolic blood pressure in men, and obesity in women were significantly and independently associated with submitral calcium. There was a 12-fold excess of atrial fibrillation in subjects with (20 of 162, 12%) compared with those without (53 of 5,532, 1%) submitral calcium.

Although reports of the clinical consequences of submitral calcium date back to the early 1900s, relatively scant attention has been given to this pathologic finding until recently. Increased use of echocardiography has helped rekindle interest in such calcium not only because it is often found on routine echocardiography, but also because it can be confused with other echocardiographic findings such as mitral stenosis and pericardial effusion.[1,2] D'Cruz et al[3] have suggested that echo-dense bands posterior to the anterior mitral leaflet (previously called mitral anular calcium) should be called posterior submitral calcium, because this pattern often represents calcium in the posterior submitral angle (between the posterior leaflet and left ventricular [LV] wall and not necessarily the anulus). Some reports have suggested that such calcium may be an important cause of mitral regurgitation and other types of cardiac dysfunction such as dysrhythmias.[4–7] Clinical reports have usually not included control groups to help ascertain whether findings associated with submitral calcium were simply due to the fact that most subjects with such calcium are elderly and thus are more likely to have various disorders.

Despite the potential importance of this apparently common problem, virtually no epidemiologic information is available regarding it. Routine echocardiography used in the prospective Framingham Study has permitted prevalence estimates and assessment of associations of submitral calcium in a population-based sample.

Methods

Study population: At the time of this report, 2,291 of the original Framingham cohort (biennial examination 16) and 3,664 offspring (examination 2) of the original cohort (and offspring spouses) had been studied by M-mode echocardiography. Detailed accounts of the sampling procedure for these populations and the clinical methods employed have been reported elsewhere.[8–10] Echocardiograms of adequate quality to assess the presence or absence of submitral calcium were obtained in 1,250 women and 819 men in the cohort group (mean age 70 ± 7 years [standard deviation], range 59 to 90). Such echocardiograms were obtained in 1,869 women and 1,756 men in the offspring-spouse group (mean age 44 ± 10 years, range 17 to 77). Quetelet's index (weight in kilograms

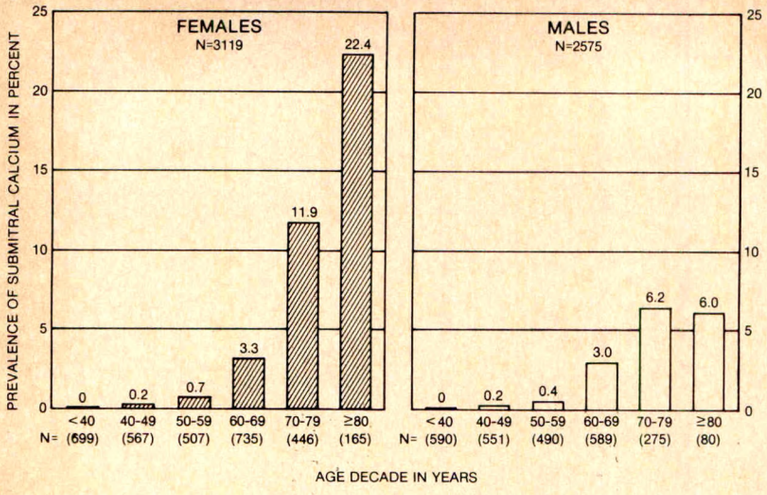

FIGURE 1. Prevalence of submitral calcium in Framingham subjects by age and sex.

divided by height in meters raised to the second power) was used as a measure of obesity. Evidence of overt cardiac disease was considered present if there were Framingham criteria for coronary disease, congestive heart failure, hypertensive heart disease, valvular heart disease (such as rheumatic heart disease), or miscellaneous "other" heart disease (such as cardiomyopathy).[10]

Echocardiographic methods: M-mode echocardiograms were performed with the subject in the partial left lateral decubitus position with the head of the bed elevated 30°. Standard techniques were employed with the transducer preferentially in the fourth intercostal space parasternally.[11] Spatial orientation was aided by the use of 2-dimensional (2-D) echocardiography in >90% of studies.

Recordings were made using an Aerotech 2.25 MHz focused transducer, a Hoffrel 201 echocardiograph interfaced with a Honeywell 1856 line scan recorder, and a Jason thermographic printer. A Hoffrel mechanical sector scanner was used for the 2-D echocardiograms. The criterion for posterior submitral calcium was the presence of an echo-dense band located immediately behind the posterior mitral leaflet (and often obscuring it). This band usually showed less motion than the endocardium of the LV posterior wall. LV wall thickness, LV internal dimensions, and left atrial dimension were measured using previously described echocardiographic methods.[12] Such measures were considered abnormal if they were greater than the published 95% confidence limits adjusted for age and body size.[12]

Statistical analyses: Where appropriate, Student's *t* test, the chi-square test, or Fisher's exact test were used to assess statistical significance. To assess the relation of submitral calcium to known risk factors for cardiac disease, univariate and multivariate logistic regression analyses were used. The regression analyses were performed using a maximum likelihood estimation and testing procedure described by Walker and Duncan.[13] Each estimated regression coefficient was tested against the alternate hypothesis that a particular partial coefficient was zero. A test outcome indicated whether the independent variable in question made a statistically significant contribution to the prediction of the dependent variable.

The dependent variable used in the multivariate analyses was the presence of posterior submitral calcium, while the independent variables were age, Quetelet's index, systolic blood pressure, blood sugar, cigarette use, and serum high- and low-density lipoprotein cholesterol levels. These independent variables, except for age, which was current, were measured 8 years before echocardiography was performed.

Results

Prevalence and association with known cardiovascular risk factors: Posterior submitral calcium was found in 162 (2.8%) of the 5,694 subjects (Fig. 1). Of the subjects with such calcium, 95% came from the 40% of the study group aged >59 years. No subject aged <45 years had submitral calcium. Women were more than twice (119 of 3,119, or 3.8%) as likely to have such calcium as men (43 of 2,575, or 1.7%), but the excess only became significant at >70 years of age when the prevalence became substantial (Fig. 1). Cardiovascular risk factors in subjects with and without submitral calcium are compared in Table I. The results of multivariate analysis to assess the independent correlates of submitral calcium are summarized in Table II.

Echocardiographic associations: Subjects with submitral calcium were significantly more likely to have increased LV wall thickness (3-fold excess), LV dilatation (2-fold excess), left atrial enlargement (3-fold excess), aortic valve calcium (5-fold excess), and reduced aortic valve leaflet motion (4-fold excess) by echocardiography. These findings remained true for age- and body size-adjusted and sex-specific comparisons of subjects with and without submitral calcium.

Only 1 of the 289 subjects with mitral valve prolapse had submitral calcium. None of the 5 subjects with prosthetic mitral valves had submitral calcium.

Associations with heart murmurs, dysrhythmias, and conduction abnormalities: The significant associations of submitral calcium with heart murmurs and atrial fibrillation (AF) are summarized in Table III. Age-decade and sex-specific comparisons indicated a 3- to 16-fold greater occurrence of submitral calcium in subjects with AF. Four of the 12 subjects with AF who had no overt evidence of cardiac or systemic disease (that is, "lone AF") had submitral calcium determined by echocardiography. Prolonged P-R intervals (>0.20 second), atrioventricular (second- or third-degree) block, bundle branch block, and artificial pacemakers

AF = atrial fibrillation.

were no more common in subjects with than in those without submitral calcium.

Discussion

This report documents a steep age-dependent gradient of prevalence of submitral calcium in a free-living population-based sample. This is consistent with clinical reports which have only rarely reported submitral calcium in subjects under age 50.[4,14–17] The 2-fold excess of submitral calcium in women versus men in the current report is also similar to that reported in clinical studies.[4,16,17] This excess in women is not simply due to women living longer than the men since age-decade specific comparisons in the present study also show this excess.

Some controversy exists regarding whether the echo-dense band behind the posterior mitral leaflet always represents calcium.[4] Joyner et al[18] have demonstrated good correlation of the echocardiographic findings with surgery and necropsy findings of calcium even when there was no radiographically demonstrable calcium. Gabor et al[2] found excellent correlation between echocardiographic and fluoroscopic findings using an image intensifier.

The association of submitral calcium with systemic arterial hypertension in the present study has also been noted in clinical studies.[2,4,16,19,20] Systemic hypertension and aortic stenosis (evidence of which was also prominent in the present study) are both associated with increased LV systolic pressure. This increased pressure might be expected to cause increased stress to be transferred to the mitral anulus by way of the mitral valve leaflets, as outlined by Fulkerson et al.[4]

The association of submitral calcium with systolic murmurs is likely to be the result of multiple factors. First, the association with systolic ejection murmurs (especially at the base and in conjunction with aortic valvular calcium and decreased leaflet motion by echocardiography) suggests a link with aortic valvular stenosis. This association has been found in reported

linical[2,4] and autopsy[15,16] series. Alternatively, aortic alve calcium and submitral calcium may occur in arallel as part of a generalized degenerative process ith neither necessarily predisposing in a causal way to he other.

The association of submitral calcium with systolic murmurs believed to be mitral in origin suggests another actor which may accelerate such calcium. Abnormal or ncreased mitral valve motion may result in anular tresses and accelerate degenerative changes there.[4] In heir clinical series of 80 subjects with submitral calcium, the average age of 11 subjects who also had mitral alve prolapse was >10 years less than the age of those ithout prolapse (64 versus 75 years).[4] Bulkley et al[21] ound that in patients with caged-ball mitral valve replacement, progressive submitral calcification could levelop within 44 months of mitral valve replacement.

Another explanation for mitral murmurs associated ith submitral calcium in the present study is that these murmurs may have been caused by the submitral calcium. Pomerance[19] found that systolic murmurs were times more common when severe submitral calcium listorted the posterior mitral cusps than when submiral calcium was slight or moderate and without mitral alve distortion. In another report, Pomerance[22] reorted postmortem findings in 173 patients >70 years ho had systolic murmurs. Seventy patients (41%) had ubmitral calcium as the sole or predominant cardiac esion.

Although several reports[2,4,23,24] of submitral calcium ave prominently featured conduction abnormalities, hese studies have usually not included control groups.)ne study that did include a large control group revealed that only right bundle branch block was signifiantly more common in subjects with submitral calcium.[14] The lack of a significant association of conduction bnormalities in the present study suggests that selective bias may account for a significant part of the reorted association between submitral calcium and onduction abnormalities. In contrast is the strong asociation of submitral calcium with AF.

Of potential significance is the finding of subjects ith submitral calcium and no other evidence of cardiac r systemic disease to explain their AF. This suggests hat a significant number of patients diagnosed as aving lone AF have submitral calcium as a possible rigin of the dysrhythmia. Mechanisms for AF might nclude left atrial enlargement causing temporal disersion of refractory periods in atrial tissue which would n turn predispose to reentrant rhythms such as AF. LV nflow obstruction could increase left atrial pressure and ead to left atrial enlargement.[16] Decreased LV compliance (associated with increased wall thickness) and mitral regurgitation or LV failure (which are associated with LV dilatation), or a combination of these would be expected to contribute to increased left atrial pressure and left atrial enlargement. Extension of the degenerative changes associated with submitral calcium into atrial tissue might interrupt atrial conduction and predispose to AF. Alternatively, increased stress on the mitral apparatus associated with AF might accelerate degenerative changes and lead to submitral calcium.

Left Ventricular Volume and Ejection Fraction Response to Exercise in Aortic Regurgitation

LYNNE L. JOHNSON, MD, ERIC R. POWERS, MD, WESLEY R. TZALL, MD, JANET FEDER, BS, ROBERT R. SCIACCA, EngScD, and PAUL J. CANNON, MD

To test the hypothesis that left ventricular (LV) performance in aortic regurgitation (AR) can be more completely characterized by measurement of LV volumes in addition to ejection fraction (EF), 27 asymptomatic patients (Group 1), and 22 symptomatic patients (Group 2), and 10 control subjects were studied at rest and during upright bicycle exercise using the first-pass technique and a multicrystal scintillation camera. LV end-diastolic volume was measured by the area-length method.

In the control group end-diastolic volume increased 14%, end-systolic volume decreased 22%, and EF increased 22% with exercise. In contrast, in Group 1 patients with AR, end-diastolic volume was elevated at rest and during exercise. The 18% decrease in end-diastolic volume during exercise was significantly different from the control response ($p < 0.01$). End-systolic volume was also elevated at rest and during exercise, but the 30% decrease during exercise was a response not significantly different from the control. Although mean EF increased 15% in these patients, EF at peak exercise was significantly lower than that in the controls. In Group 2 patients with AR, resting EF was reduced, the EF response to exercise was abnormal, and end-diastolic and end-systolic volume responses to exericse were significantly different from those in Group 1: end-diastolic volume did not change and end-systolic volume increased. In contrast to the fairly uniform volume responses among all Group 1 patients, there were 2 subgroups based on volume changes within Group 2: 7 of 22 had a decrease in end-diastolic volume and end-systolic volume during exercise and 8 of 22 showed an increase in end-diastolic and end-systolic volume during exercise. In conclusion, LV volumes at rest and exercise give more information about LV functional reserve in symptomatic patients with AR than do EF responses alone, and may be useful in separating symptomatic patients who show a normal end-systolic volume response to exercise from those in whom worsening failure develops during exercise.

The results after valve replacement in symptomatic patients with aortic regurgitation (AR) are variable. Some patients fail to show an improvement in left ventricular (LV) function or may actually have further deterioration after valve replacement.[1] Other data suggest that resting ejection fraction (EF) improves after aortic valve replacement but that the EF response to exercise remains abnormal.[2] However, prosthetic valves are not perfect.[3] Degeneration and calcification of porcine valves have occurred more frequently in younger patients.[4,5] Because isolated AR due to rheumatic fever is most common in young men,[6] a real clinical dilemma arises concerning the optimal timing for aortic valve replacement.

Radionuclide angiography has been a useful method for noninvasive measurement of cardiac function in patients with AR. Borer et al,[7] using gated blood pool scintigraphy at rest and during supine exercise, found a variable EF response among asymptomatic patients, some patients showing an increase and others a decrease in EF during exercise. However, EF alone is both preload- and afterload-dependent. Ventricles with volume overload have abnormal loading conditions, and therefore indexes of LV function more independent of preload than EF are important in these conditions.

It has been shown experimentally that a more complete characterization of LV performance can be achieved by measurement of LV end-diastolic and end-systolic volumes.[8] Therefore, the objective of the present study was to define, using first-pass radionuclide angiography, the response of LV volumes to upright exercise in asymptomatic and symptomatic patients with AR. The data indicate that the LV volume response to exercise delineates subgroups within the symptomatic population. In addition, this report includes the results of a validation of the radionuclide measurements of LV volumes against green dye cardiac output and contrast ventriculography performed in our laboratory.

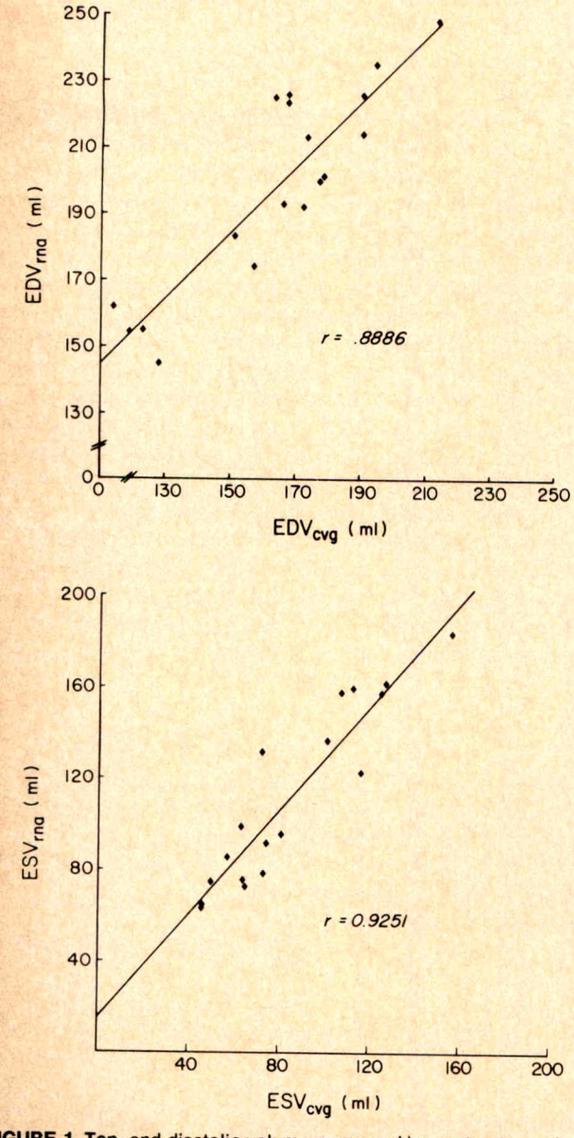

FIGURE 1. Top, end-diastolic volume measured by contrast ventriculography (EDV_{cvg}) is plotted against end-diastolic volume measured by radionuclide angiography (EDV_{rna}). **Bottom,** end-systolic volume measured by contrast ventriculography (ESV_{cvg}) is plotted against end-systolic volume measured by radionuclide angiography (ESV_{rna}).

Methods

Patient selection: All patients with AR studied in the Nuclear Cardiology Laboratory at Presbyterian Hospital from January 1979 through January 1981 were considered candidates for the study. All patients with coexisting valvular lesions, including aortic stenosis, mitral stenosis, mitral regurgitation, and coronary artery disease, were excluded. In addition, 10 healthy normal control subjects were studied.

The group consisted of 42 men and 7 women aged 17 to 78 years. All patients were referred for study because of clinical signs of AR including diastolic murmur and wide pulse pressure. Forty-one of the 49 patients had left ventricular hypertrophy on electrocardiography based on Romhilt-Estes criteria, and 40 of 49 had enlarged hearts on chest X-ray based on a cardiothoracic ratio >0.5. Twenty-seven patients were asymptomatic (Group 1) and 22 were symptomatic with either dyspnea or chest pain or both (Group 2). Twenty-six patients, including 19 of 22 patients in Group 2, had cardiac catheterization. The results of catheterization documented isolated 3+ to 4+ AR.

In the noncatheterized group, coexistent valvular lesions were ruled out by echocardiography. All patients who had cardiac catheterization had normal coronary arteries, including 25 of the 31 patients over 35 years of age. Six other patients who were over 35 and who did not have catheterization had normal EF responses to 85% age-predicted maximal heart rate and none had angina.

The 10 control subjects were all healthy male volunteers aged 22 to 46 years with a mean age of 29 ± 7 (standard deviation). None had any cardiac symptoms and all had normal cardiovascular examinations.

First-pass radionuclide angiography: Radionuclide angiography at rest and during upright bicycle exercise was performed by the first-pass technique as previously described.[9] A multiple crystal gamma camera (System Seventy-Seven, Baird Atomic) equipped with a 1-inch collimator, was used for data acquisition. Exercise was begun at the work load equivalent to stage 1 of the Bruce protocol and increased by 150 or 300 kpm/min increments and terminated by symptoms of dyspnea, leg fatigue, or achievement of 85% of age-predicted maximal heart rate. Blood pressure was measured on a cuff sphygmomanometer. Lead CS_5 of the electrocardiogram was monitored continuously and recorded at 1-minute intervals using a Hewlett-Packard recorder. At peak exercise, radionuclide angiography was repeated while the patient continued to pedal. LVEF was determined using a modification[9] of the method of Marshall et al.[10]

Left ventricular volume measurements: The LV border and the intensity and spatial distribution of background counts were defined by computer analysis..[11] An LV region of interest was determined on the basis of identification of count changes during the cardiac cycle. A representative cardiac cycle was constructed from the summation of the end-diastolic and end-systolic beats in the LV region of interest. Background was determined by a computer algorithm.[11] The LV border was defined to include all counts in the LV end-diastolic image above 21% of the highest count in the image. The use of this lower level of 21% is based on phantom studies performed with a 1.5-inch collimator.[12]

LV volumes were measured using a modification of the single plane area-length method.[13] The area of the LV silhouette was planimetered using a Hewlett-Packard desk top calculator (model 9820A). End-diastolic volumes were calculated from the equation for an ellipsoid of revolution for the single anterior projection in which end-diastolic volume (EDV) = $0.85\ A^2L$, where A = area and L = length of the major axis. Correction was made for image magnification by multi-

plying the planimetered area by the ratio of the measured width of the hard copy display of the entire collimator field of view and the measured width of a row of crystals on the detector (true area = measured area × 2.2).

A study was carried out in our laboratory to validate the area-length method for calculating end-diastolic volume from radionuclide angiograms (EDV_{rna}) against contrast ventriculography (EDV_{cvg}). In 18 patients without valvular regurgitation undergoing right and left heart catheterization, cardiac output was measured by green dye, and a first-pass radionuclide angiogram in the anteroposterior projection was performed using a multicrystal scintillation camera located in the catheterization laboratory. Immediately thereafter, a contrast left ventriculogram was performed in the shallow (15° to 20°) right anterior oblique projection.

An excellent correlation was found between EDV_{cvg} and EDV_{rna} with an r value of 0.89 and a standard error of the estimate (SEE) of 14.5 ml (Fig. 1, top). The radionuclide volumes consistently overestimated the contrast ventriculographic volumes. A regression equation was derived for the radionuclide data: $y = 0.84x - 10.3$ in which y = corrected end-diastolic volume and x = measured radionuclide volume. Stroke volume was calculated as end-diastolic volume times EF, and end-systolic volume as end-diastolic volume minus stroke volume. When the ESV_{rna} was plotted versus ESV_{cvg} there was an excellent correlation, with an r value of 0.93 and an SEE of 15.5 ml (Fig. 1, bottom).

To test the reproducibility of calculated LV volumes in patients with cardiac dilatation, 8 patients with cardiac dilatation had serial rest and exercise studies. The standard deviation of replicate measurements was ±7.1 ml for ΔEDV and ±8.0 ml for ΔESV, resulting in 95% confidence limits, close to the value of 15 ml reported by Scholz et al.[11] Therefore, a significant change for any individual value of LV volumes was defined as a change >15 ml.

Of the 21 patients with AR who were catheterized, 10 met the following criteria: (1) radionuclide studies performed within 3 months of catheterization, and (2) contrast ventriculograms of good enough quality for volume measurements. In these 10 patients, when end-diastolic volumes measured by radionuclide angiocardiography was compared with end-diastolic volumes measured by contrast ventriculography, there was a good correlation, with an r value of 0.93.

Statistical analysis: Tests of hypotheses relating to group means were performed by analysis of variance or by the nonparametric Kruskal-Wallis procedure when the variables were not normally distributed within groups, as was the case for LV volumes.[14] Correlations between LV volume and EF were determined using the Wilcoxon procedure. Differences were termed significant if the test statistic exceeded the critical value for the 5% level.

Results

Control subjects: The results of the study are presented in Tables I to III and Figures 2 to 5. In the control subjects the exercise duration was 12 ± 2 minutes and total work load achieved was 86 ± 25 kJ. Heart rate increased during exercise from 80 ± 11 to 162 ± 14 beats/min. Systolic blood pressure increased during exercise from 124 ± 10 to 174 ± 27 mm Hg, whereas diastolic blood pressure did not change significantly (80 ± 7 mm Hg at rest and 78 ± 7 mm Hg during exercise). End-diastolic volume at rest was 64 ± 16 ml/m² and increased during exercise to 73 ± 17 ml/m² ($p < 0.05$) (Fig. 2). End-systolic volume was 27 ± 10 ml/m² at rest

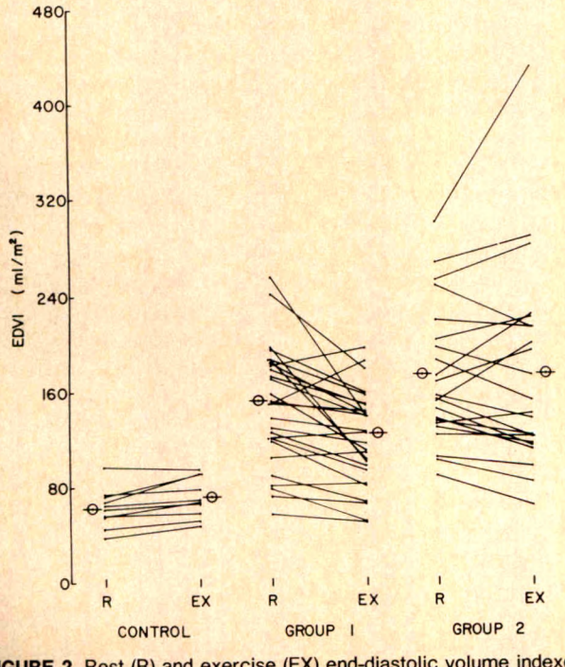

FIGURE 2. Rest (R) and exercise (EX) end-diastolic volume indexes (EDVI) for controls and for 2 AR patient groups are shown. EDVI increased significantly in controls ($p < 0.05$), decreased significantly in AR Group 1 ($p < 0.01$), and did not change significantly in AR Group 2. Mean values are indicated by **circles.**

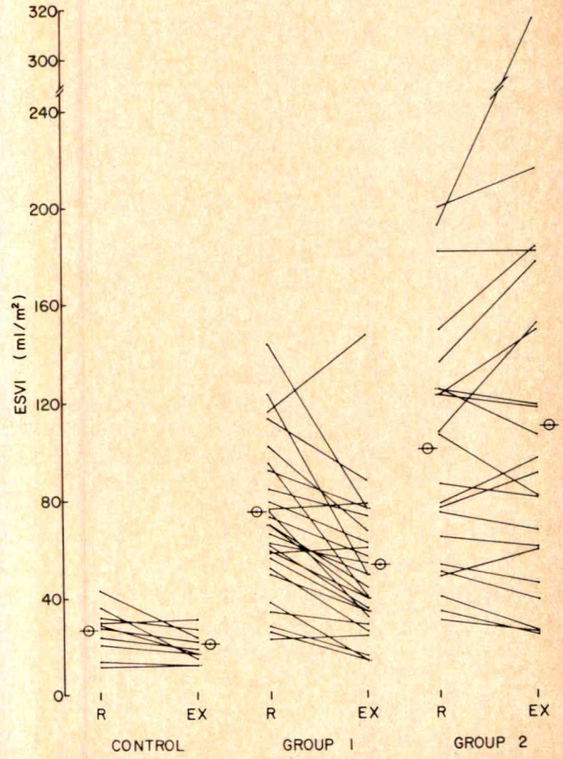

FIGURE 3. Rest (R) and exercise (EX) end-systolic volume indexes (ESVI) for controls and 2 AR patient groups are shown. ESVI decreased significantly in controls ($p < 0.05$), decreased significantly in AR Group 1 ($p < 0.01$), and did not change significantly in AR Group 2.

ΔEDVI = change in end-diastolic volume index; ΔEF = change in ejection fraction; ΔESVI = change in end-systolic volume index; EX = exercise; LVEDVI = left ventricular end-diastolic volume index; LVEF = left ventricular ejection fraction; LVESVI = left ventricular end-systolic volume index; Pt = patient; R = rest; SD = standard deviation; SVI = stroke volume index; ΔSVI = change in stroke volume index.

and decreased to 21 ± 6 ml/m² during exercise ($p < 0.05$) (Fig. 3). Therefore, stroke volume increased from 37 ± 8 ml/m² to 52 ± 12 ml/m² ($p < 0.05$) and EF increased from 59 ± 6% to 72 ± 5% ($p < 0.05$) (Fig. 4).

Clinical characteristics of patients with AR: The patients in Group 2 were significantly older than those in Group 1 (47 ± 17 versus 38 ± 15 years, $p < 0.01$). A similar number of patients in Group 2 had LV hypertrophy on electrocardiogram (20 of 22, 91%) as in Group 1 (22 of 27, 81%). A similar number of patients in Group 2 had enlarged hearts on chest X-ray (17 of 22, 77%) as in Group 1 (18 of 27, 67%).

AR Group 1: Exercise duration in AR Group 1 was 10 ± 2 minutes, significantly less than that in the controls ($p < 0.01$); the work load achieved, 52 ± 22 kJ, was also significantly less than that in the controls ($p < 0.01$) (Table I). Diastolic time per minute decreased from 35 ± 4 s/min to 30 ± 5 s/min ($p < 0.01$).

In AR Group 1, the resting heart rate of 80 ± 16 beats/min was not significantly different from that of the control subjects. During exercise, heart rate increased to 149 ± 25 beats/min, a value also not significantly different from that of the controls. At rest, the systolic blood pressure (139 ± 17 mm Hg) was significantly higher and the diastolic blood pressure (63 ± 19 mm Hg) lower in AR Group 1 than in the controls ($p < 0.05$). However, during exercise the systolic and diastolic blood pressure (195 ± 25 mm Hg, 81 ± 15 mm Hg) was not significantly different from that of the control subjects.

In AR Group 1, the end-diastolic volume at rest was significantly greater than that of the controls ($p < 0.01$) (Table I, Fig. 2) and decreased during exercise to a value that was significantly higher than the exercise end-diastolic volume observed in the control subjects. The decrease in end-diastolic volume during exercise in AR Group 1 was a significantly different response from the increase during exercise observed in the control subjects ($p < 0.01$) (Fig. 5). The end-systolic volume at rest in Group 1 was significantly larger than that in the control subjects ($p < 0.01$) (Fig. 3). During exercise, end-systolic volume decreased in AR Group 1, but the value for exercise end-systolic volume was significantly larger than the end-systolic volume at peak exercise observed in the control subjects ($p < 0.01$). The change in end-systolic volume during exercise was not significantly different between the 2 groups (Fig. 5).

The EF at rest in AR Group 1 was not significantly different from that of the control subjects, and it increased during exercise ($p < 0.05$) (Fig. 4). Although the exercise EF in AR Group 1 was significantly lower than that of the control subjects, the change in EF observed during exercise was not significantly different between the 2 groups.

Twenty of the 27 patients in AR Group 1 showed a significant decrease in end-diastolic volume from rest to exercise (Table I). Twenty-two of 27 showed a significant decrease in end-systolic volume. Only 2 patients had a significant increase in end-diastolic volume during exercise (Patients 9 and 27). Only 1 patient had a sig-

ΔEDVI = change in end-diastolic volume index; ΔEF = change in ejection fraction; ΔESVI = change in end-systolic volume index; EX = exercise; LVEDVI = left ventricular end-diastolic volume index; LVEF = left ventricular ejection fraction; LVESVI = left ventricular end-systolic volume index; Pt = patient; R = rest; SD = standard deviation; SVI = stroke volume index; ΔSVI = change in stroke volume index.

TABLE III LV Volume Responses in Symptomatic AR Patients

	ΔESV		
ΔEDV	Decrease	No Change	Increase
Decrease	7	4	0
No change	0	2	0
Increase	1	0	8

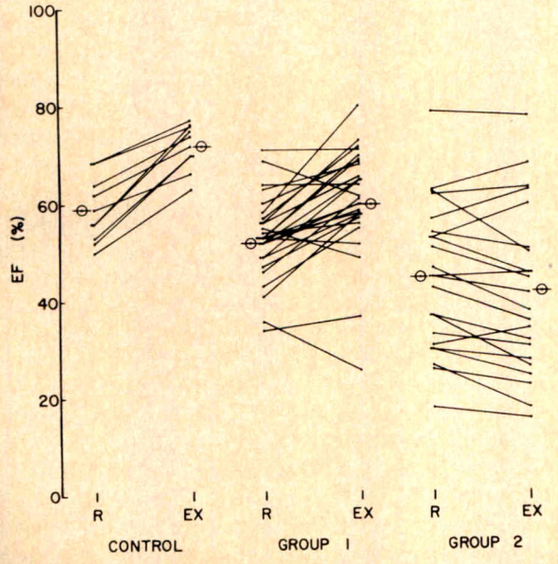

FIGURE 4. Rest (R) and exercise (EX) ejection fraction for controls and 2 AR patient groups are shown. EF increased significantly in AR Group 1 ($p < 0.01$) and showed a small but significant decrease in AR Group 2 ($p < 0.05$).

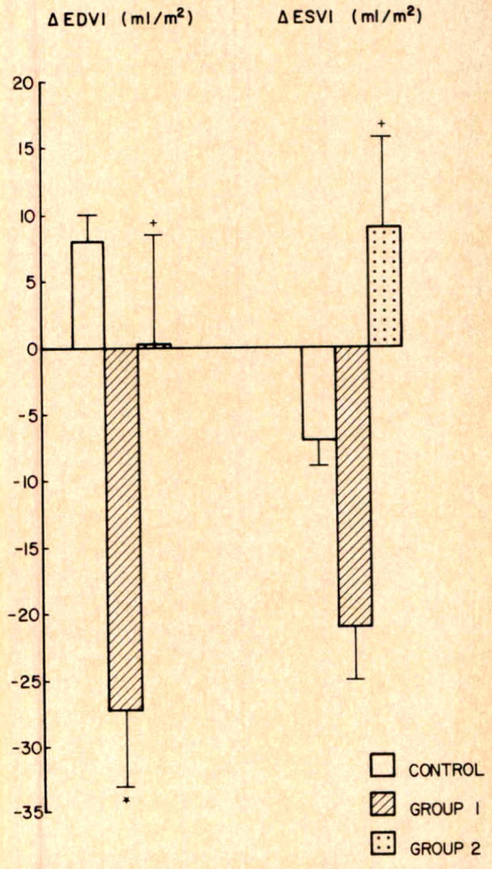

FIGURE 5. The changes in LV volume are depicted for controls and the 2 AR patient groups. The **error bars** represent 1 standard of the mean, the **asterisk** denotes a value significantly different from that in the controls, and the **plus signs** denote a value significantly different from that in Group 1. Abbreviations as in Figures 2 and 3.

nificant increase in end-systolic volume (Patient 27). This patient had a concomitant decrease in EF and an increase in end-diastolic volume.

AR Group 2: Exercise duration in AR Group 2 was 7 ± 2 minutes, significantly lower than that of the controls ($p < 0.01$) and lower than that of AR Group 1 patients ($p < 0.05$). Total work load achieved was 31 ± 16 kJ, significantly lower than that of the controls ($p < 0.01$) and lower than that of AR Group 1 patients ($p < 0.01$). Diastolic time per minute during exercise in AR Group 2 decreased from 34 ± 4 s/min to 31 ± 4 s/min ($p < 0.01$). The decrease in diastolic time per minute during exercise was not significantly different from that of AR Group 1 patients (−3 ± 3 versus −5 ± 6 s/min).

In AR Group 2 the heart rate at rest (82 ± 14 beats/min) was not significantly different from that of the control subjects or of AR Group 1 patients. During exercise the heart rate increased to 136 ± 27 beats/min, a value less than that of the controls ($p < 0.01$) but not significantly different from that of AR Group 1 patients. At rest systolic blood pressure in AR Group 2 (143 ± 25 mm Hg) was significantly higher and the diastolic blood pressure (63 ± 22 mm Hg) lower than the control subjects; pressures increased during exercise to 190 ± 34 and 69 ± 24 mm Hg, respectively. During peak exercise the systolic and diastolic blood pressures were not significantly different among the 3 groups.

In AR Group 2, the end-diastolic volume at rest was significantly greater than that of the controls ($p < 0.01$), but not significantly different than that of Group 1 patients (Fig. 2). End-diastolic volume did not change during exercise in this group, a response that was significantly different from the change during exercise in AR Group 1 ($p < 0.01$) (Fig. 5). The end-systolic volume at rest in AR Group 2 patients was significantly larger than that of the controls ($p < 0.01$) but not significantly different from that in AR Group 1 (Fig. 3). End-systolic volume increased during exercise in AR Group 2 patients to a value significantly larger than that of the controls ($p < 0.01$), and also significantly larger than that in AR Group 1 ($p < 0.01$). In addition, the change in end-systolic volume during exercise in AR Group 2 was significantly different from the change during exercise in AR Group 1 ($p < 0.01$) (Fig. 5).

In AR Group 2 the resting EF was significantly lower than that in AR Group 1 and that in the control subjects. During exercise the EF decreased slightly, but significantly ($p < 0.05$) (Fig. 4). The ejection fraction at peak exercise was significantly lower in AR Group 2 than in AR Group 1 or in control subjects.

Within AR Group 2, there were several subgroups based on combined LV volume EF responses (Tables II and III). Seven patients (Patients 1, 3, 4, 10, 11, 13, and 18) had a significant decrease in end-diastolic volume and end-systolic volume. Of this group, 2 (Patients 1 and 3) had a borderline normal EF fraction response to exercise. Eight patients (Patients 5, 6, 15, 16, and 19–22) had a significant increase in end-diastolic and end-systolic volume. Of this group, 7 (Patients 6, 15, 16, and 19–22) had reduced resting ejection fractions and a further decrease in ejection fraction during exercise. Of the remaining 7 patients in AR Group 2, the volume response was variable. Four (Patients 8, 9, 12, and 14) had a significant decrease in end-diastolic volume with a smaller nonsignificant decrease in end-systolic volume; 2 (Patients 2 and 17) had no significant change in either end-diastolic or end-systolic volume, and 1 (Patient 7) had a decrease in end-diastolic volume and an increase in end-systolic volume (Table III).

Discussion

The mean values for end-diastolic volume at rest and during exercise obtained in the control subjects were not different from those reported by Rerych et al[13] in normal volunteers using a similar upright bicycle exercise protocol and the first-pass radionuclide technique.[13] In addition, the directional changes in all parameters were similar to those reported by Poliner et al[15] who compared the effects of supine and upright exercise on LV volumes and EF in normal subjects.

The results in asymptomatic patients with AR differ from those reported by Dehmer et al.[16] In their study, end-diastolic and end-systolic volumes at rest in asymptomatic patients with AR were significantly lower than the values in our asymptomatic AR group. During supine exercise there was no change in mean end-diastolic or end-systolic volumes or EF in the asymptomatic patients with AR studied by Dehmer et al,[16] whereas EF increased and end-diastolic and end-systolic volume decreased in our Group 1. One possible explanation for these different results are differences in protocol (supine versus upright exercise). Recently, Marx et al[17] showed that patient position significantly influences the exercise EF response in AR, probably because of differences in LV loading between the supine and upright positions. Another possible explanation is differences in patient selection. Sixty-seven percent of patients in our asymptomatic AR group had cardiac enlargement on chest X-ray and 81% had LV hypertrophy on the electrocardiogram. These findings correlated with the elevated sting end-diastolic volumes. The value for resting end-systolic volume in our asymptomatic AR Group 1 patients of 71 ± 31 ml/m^2 was not significantly different from the value of 62 ± 14 ml/m^2 that was observed for 10 asymptomatic patients with AR studied by contrast ventriculography and reported on by Osbakken et al.[18]

Regurgitant volume is an important contributor to end-diastolic volume in patients with AR. During exercise, diastolic time per minute decreased 5 seconds in AR Group 1 patients. The reduction in regurgitant volume is the most likely explanation for the large decrease in end-diastolic volume which occurred during exercise. This interpretation is consistent with other studies of patients with AR during pacing in which LV end-diastolic pressure decreased as diastolic time per minute was reduced by the faster heart rate.[19]

End-systolic volume was increased at rest in asymptomatic Group 1 patients with AR. Other investigators have observed that cardiac enlargement in volume overloaded hearts is accompanied by elevations in both end-diastolic and end-systolic volumes with maintenance of a normal relation between stroke volume and end-diastolic volume.[20]

The fact that mean end-systolic volume was increased not only at rest but also at peak exercise in Group 1 patients and that the exercise EF was below that of the controls may indicate impairment of myocardial contractility in Group 1 patients. In the study of Dehmer et al,[16] mean end-systolic volume at peak exercise was also higher than that in the controls. In the ventriculographic study of Osbakken et al,[18] plots of resting end-systolic stress and end-systolic volume index were made for control subjects and for asymptomatic and symptomatic patients with AR. These investigators found that the data for the 3 groups fell on 3 separate curves, with the curve for the asymptomatic patients with AR intermediate between the other 2 groups.

The decrease in end-systolic volume during exercise in the asymptomatic AR group was greater than that in the controls; however, when expressed as a percentage of resting end-systolic volume, there was no difference from the control group. The decrease in end-systolic volume seen in upright exercise in normal subjects is a result of the combination of the effects of increased myocardial contractility and decreased afterload.[21] Therefore, the decrease in end-systolic volume with exercise in Group 1 patients suggests either that afterload during exercise is lower in this group than in Group 2 patients who show an increase in end-systolic volume during exercise, or that the ventricles of Group 1 patients are able to respond to increased circulating catecholamines during exercise, or both.

In contrast to the fairly homogeneous volume response in Group 1, inspection of the data (Fig. 2, 3, and 5) indicate that the responses to exercise in Group 2 were not uniform. Two distinct subgroups can be identified. In 1 subgroup (7 patients) end-diastolic volume decreased as diastolic time per minute and probable net regurgitation decreased. In this same subgroup end-systolic volume simultaneously decreased. In the second subgroup of 8 patients in AR Group 2, concomitant increases in both end-diastolic and end-systolic volumes and a decrease in EF during exercise indicate the effect of exercise in inducing a worsening of preexisting LV failure.

In summary, there are distinctly different patterns of LV volume change during exercise among patients with AR. There is a younger, asymptomatic subgroup in whom the end-diastolic volume decreases during exercise as diastolic time per minute decreases with rapid heart rate, suggesting that regurgitant volume is a major determinant of resting end-diastolic volume in this group. In this same group end-systolic volume decreases while EF increases, suggesting a positive inotropic response to exercise. In contrast, among older, symptomatic patients with AR, there is a subgroup with a pattern of volume change similar to that in Group 1, and another subgroup in whom LV failure clearly develops during exercise. Further study is needed to determine whether LV volume response during exercise in patients with AR is a useful parameter that can be combined with other parameters to help predict the optimal time for aortic valve replacement.

Atrial Systole and Left Ventricular Filling in Hypertrophic Cardiomyopathy: Effect of Verapamil

ROBERT O. BONOW, MD, TERRI M. FREDERICK, RN, STEPHEN L. BACHARACH, PhD, MICHAEL V. GREEN, MS, PAMELA W. GOOSE, RN, BARRY J. MARON, MD, and DOUGLAS R. ROSING, MD

Many patients with hypertrophic cardiomyopathy (HC) have impaired left ventricular (LV) rapid diastolic filling. To quantitate the contribution of atrial systole to LV filling, we used radionuclide angiography to study 30 normal volunteers and 42 patients with HC before and after oral administration of verapamil (320 to 560 mg/day). LV time-activity curves were constructed by combined forward and reverse gating from the R wave, and the onset of atrial systole was determined by the P-R interval. The percent of LV stroke volume filled during rapid diastolic filling and atrial systole was then computed. Peak LV filling rate during rapid diastolic filling was expressed in end-diastolic volume (EDV)/second. Peak rate of rapid diastolic filling was not different in normal patients and those with HC (3.3 ± 0.6 versus 3.3 ± 1.1 EDV/s) and was within the normal range in 34 patients with HC (81%). However, the contribution to LV filling volume by rapid diastolic filling was diminished in patients with HC (83 ± 7% normal, 67 ± 17% HC, $p < 0.001$) and the contribution of atrial systole was increased (16 ± 8% normal, 31 ± 18% HC, $p < 0.001$). LV filling volume during atrial systole was above the upper normal limit of 31% in 17 patients (40%), including 13 patients with a normal peak filling rate. After verapamil, peak filling rate increased (to 4.2 ± 1.2 EDV/s, $p < 0.001$), percent LV filling during rapid diastolic filling increased (to 83 ± 7%, $p < 0.001$), and percent LV filling during atrial systole decreased (to 16 ± 9%, $p < 0.001$). Percent LV filling volume during atrial systole was abnormal after verapamil in only 3 patients (7%). Hence, although the peak rate of rapid diastolic filling may be normal in patients with HC, the contribution to LV filling by rapid diastolic filling is reduced and that of atrial systole is thereby increased. Increased rate and magnitude of rapid diastolic filling during verapamil is associated with decrease and normalization of the contribution of atrial systole to LV filling. These data suggest that many patients with HC are at risk of hemodynamic decompensation with the onset of atrial fibrillation or other tachyarrhythmias and loss of the atrial contribution to LV filling. This risk may be reduced during verapamil therapy.

Many patients with hypertrophic cardiomyopathy (HC) have abnormal left ventricular (LV) filling during early diastole, manifested by impaired isovolumic relaxation, reduced rapid diastolic filling periods, and diminished rate of rapid diastolic filling.[1–7] These factors may reduce the contribution of rapid diastolic filling to total LV filling volume, and the contributions of slow diastolic filling or atrial systole to LV filling might then be increased. Because atrial fibrillation, atrial flutter, and ventricular tachycardia are common complications of HC,[8–10] an increased dependence on atrial systole for LV filling may place many patients at risk of hemodynamic decompensation with the onset of these arrhythmias and the loss of synchronized atrial contraction.

In the current study, we used LV time-activity curves obtained by radionuclide angiography to quantitate the contributions of rapid diastolic filling and atrial systole to LV filling in patients with HC. We have also studied the effects of oral verapamil therapy to determine if improved isovolumic relaxation[11] and an increased rate of rapid diastolic filling[7] observed during verapamil administration are associated with a reduction in the contribution of atrial systole to LV filling.

Methods

Patient selection: We studied 57 patients, aged 21 to 69 years (mean 44), with HC. All patients were in normal sinus rhythm. In each patient, the diagnosis of HC was based on echocardiographic demonstration of a hypertrophied, nondilated left ventricle in the absence of other acquired or congenital heart disease.[12] Disproportionate septal thickening with respect to the LV free wall (septal-to-free wall ratio ≥1.3) was identified in 53 patients. In the other 4 patients, 2-dimensional echocardiography demonstrated regional disproportionate hypertrophy in the posterior septum or anterolateral LV free wall.[13] Cardiac catheterization in 55 patients demonstrated LV outflow tract obstruction at rest (gradient ≥30 mm Hg) in 21 patients (38%). In 25 patients (45%) without resting obstruction, ≥30 mm Hg subvalvular gradient developed during provocation with amyl nitrate inhalation, intravenous isoproterenol infusion, or the Valsalva maneuver. In 9 patients (16%), no gradient was elicited either at rest or with provocation. In both patients not catheterized, systolic anterior motion of the anterior mitral valve was demonstrated at rest by echocardiography.

We also studied 30 normal volunteers, aged 21 to 63 years, to determine the normal values for the radionuclide measurements. These subjects had no evidence of cardiovascular or pulmonary disease. Cardiac catheterization was not performed, but physical examination (including blood pressure), chest X-ray, electrocardiography, and M-mode echocardiography gave normal results in all subjects.

Drug administration: In patients with HC, control radionuclide studies were performed ≥48 hours after the cessation of propranolol and all other cardiac medications except diuretics. After the control study, oral verapamil was administered. Therapy was initiated at a dose of 240 mg daily in divided doses and was gradually increased every 36 to 48 hours to a dose of 480 to 640 mg daily. The final verapamil dosage was determined by the clinical response of each patient and was limited in some patients because of atrioventricular dissociation, Mobitz I second-degree atrioventricular block, or systemic hypotension. The final daily verapamil dose was 320 mg in 10 patients (17%), 360 mg in 15 patients (26%), 400 mg in 1 patient (2%), 480 mg in 15 patients (26%), 560 mg in 1 patient (2%), and 640 mg in 1 patient. Radionuclide angiography was repeated after each patient received what was considered the optimal verapamil dosage for at least 36 hours.

Gated equilibrium blood pool scintigraphy: Radionuclide cineangiography was performed at rest using red blood cells labelled in vivo with 15 to 20 mCi of technetium-99m.[14] Blood pressure was measured by sphygmomanometry in the supine position at the time of each radionuclide study. Imaging was performed in the supine position with a conventional Anger camera equipped with a high-sensitivity, parallel-hole collimator oriented in a modified left anterior oblique position to isolate the left ventricle from other cardiac structures. The cardiac image sequence spanning the average cardiac cycle was constructed from several hundred cardiac cycles by computer-based electrocardiographic gating, using list-mode data acquisition (framing rate up to 100 images/s).[7,15] High-temporal resolution LV time-activity curves were generated from the cardiac image sequence after background correction. Extrasystolic and postextrasystolic cardiac cycles were excluded, and the diastolic portion of the time-activity curve was constructed by combined forward-gating and reverse-gating from the R wave.[16,17] The time-activity curve represents a measure of relative LV volume changes with time throughout the cardiac cycle.

LV ejection fraction was automatically determined by computer analysis of the time-activity curve.[15] Peak rate of LV filling during the rapid filling phase of diastole was computed by fitting a third-order polynomial function to the rapid filling portion of the time-activity curve, using a least-squares technique.[7,18] Peak filling rate was computed in counts per second, normalized for the number of counts at end-diastole, and expressed as end-diastolic volume per second (EDV/s). The time to peak filling rate was measured from end-systole (minimal volume on the time-activity curve) to the time of peak left ventricular filling rate.

Two other indexes of LV diastolic filling were also computed: relative LV filling volume during rapid diastolic filling and relative filling volume during atrial systole. These measurements were obtained in all 30 normal volunteers. However, these measurements could be performed in only 42 patients with HC in whom the rapid diastolic filling and atrial systolic portions of the time-activity curve were clearly separated by a diastasis interval (or slow filling phase) (Fig. 1).

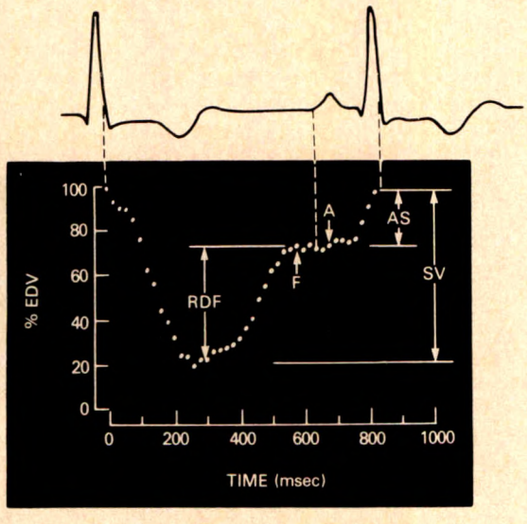

FIGURE 1. Left ventricular time-activity curve obtained at rest in a patient with hypertrophic cardiomyopathy. Heart rate is 70 beats/min. Each point represents 20 ms. Termination of rapid diastolic filling (**arrow F**) is determined visually by 2 observers. Onset of atrial systole (**arrow A**) is determined automatically by subtracting the P-R interval (140 ms) and the interval from the onset of QRS to point of R-wave gating (60 ms) from the cardiac cycle length and then adding 40 ms for assumed atrial electrical-mechanical delay. Left ventricular filling volume during rapid diastolic filling (RDF) and atrial systole (AS) are expressed relative to total stroke volume (SV). EDV = end-diastolic volume.

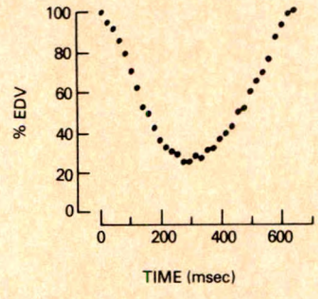

FIGURE 2. Time-activity curve obtained at rest from a patient with hypertrophic cardiomyopathy. The heart rate is 96 beats/min. Unlike the time-activity curve in Figure 1, no diastasis interval is evident, and termination of rapid diastolic filling cannot be differentiated from onset of atrial systole. EDV = end-diastolic volume.

In the other 15 patients, no diastasis interval was evident under control conditions, and rapid diastolic filling and atrial systole could not be distinguished (Fig. 2). Patients without a discernible diastasis interval had a faster heart rate than did patients with a diastasis interval (92 ± 14 [SD] versus 71 ± 12 beats/min; $p < 0.001$), but did not differ with respect to age, sex, or indexes of LV function such as ejection fraction or peak filling rate. Eleven of 15 patients without a discernible diastasis interval (73%) had a heart rate ≥90 beats/min, which compares with only 3 of 42 patients with a diastasis interval (7%). The 15 patients in whom rapid diastolic filling could not be distinguished from atrial systole under control conditions were excluded from further analysis. Thus, data regarding relative LV filling volumes during rapid filling and during atrial systole before and after verapamil were computed in 42 patients. There were 26 men and 16 women.

Left ventricular filling during rapid diastolic filling: The termination of the rapid filling phase of the time activity curve was determined by visual inspection (Fig. 1), and the relative LV filling volume occurring during rapid diastolic filling was computed as a percentage of total LV stroke volume. To minimize the effect of random noise in the curve, the volume represented by the point on the curve selected as termination of rapid filling was averaged with the volume represented by the points on either side of the point in question to yield a 3-point average. Because this visual selection process is subjective, each curve was analyzed by 2 independent observers, both of whom were unaware of whether the curve represented a normal study, a control study, or a verapamil study. Percent of LV filling volume during rapid filling for each curve was chosen as the average of the 2 observers' calculations. A close agreement was reached between the 2 observers for normal volunteers ($r = 0.97$, standard error [SE] = 1.75) and for patients with HC ($r = 0.89$, SE = 6.90).

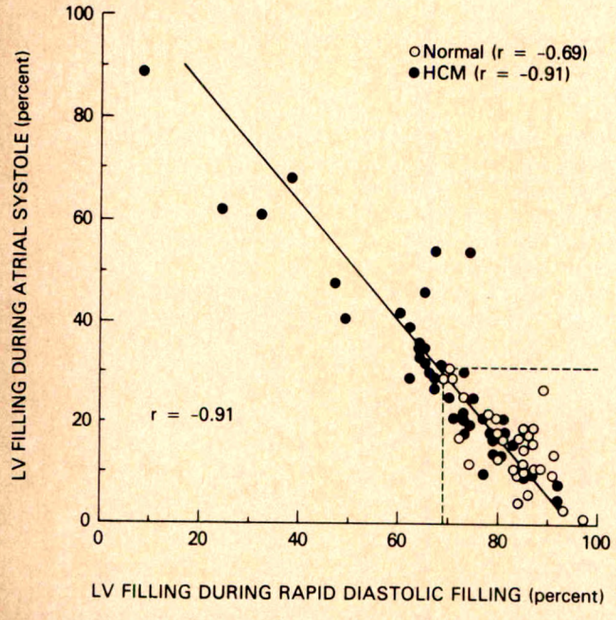

FIGURE 3. Left ventricular (LV) filling volume during atrial systole plotted as a function of LV filling volume during rapid diastolic filling in normal volunteers (**open circles**) and patients with hypertrophic cardiomyopathy (HCM) (**closed circles**). Both filling volumes are expressed as percentages of total LV stroke volume. **Dashed lines** indicate lower limit of normal for filling during rapid diastolic filling (69%) and upper limit of normal for filling during atrial systole (31%). The **solid line** indicates the linear regression line.

Left ventricular filling during atrial systole: To determine the onset of atrial systole, the total duration of the P-R interval (onset of P wave to onset of QRS) plus the interval from the onset of QRS to instant of R-wave gating (peak negative R-to-S transition) was measured to the nearest 20 ms from an electrocardiographic rhythm strip obtained during the radionuclide data acquisition. This sum was subtracted from the cardiac cycle length to indicate the point on the time activity curve representing the onset of atrial electrical activation; 40 ms was added to this value to account for atrial electrical-mechanical delay, and this new point on the curve was chosen as the onset of mechanical atrial systole (Fig. 1). Relative LV filling during atrial systole was then computed as a percentage of the total LV stroke volume. As in the determination of rapid diastolic filling volume, a 3-point average was performed about the point on the curve selected as the onset of atrial systole to minimize the influence of random noise. The P-R interval and the interval from the onset of QRS to the instant of R-wave gating were measured manually without knowledge of whether a study was performed during control conditions or during verapamil administration. The remaining computations were performed automatically by computer processing. A good correlation ($r = 0.91$, SE = 6.90) was observed between the percentage of LV filling during rapid diastolic filling measured visually (average of 2 observers) and the percentage of LV filling during atrial systole measured automatically (Fig. 3).

Reproducibility of radionuclide measurements: The reproducibility of LV ejection fraction, peak filling rate, and time to peak filling rate by radionuclide angiography have been reported previously in patients with HC.[7] To determine the reproducibility of the percentage of LV filling during rapid diastolic filling and during atrial systole, we studied 25 other patients with HC in whom the diagnosis was established by M-mode echocardiographic criteria. Each patient had a septal-to-free wall ratio >1.3. Two radionuclide studies were performed after a single injection of technetium-99m ≥48 hours after the cessation of all cardiac medications.

Statistical methods: Data were analyzed by the *t* test, using unpaired and paired data as appropriate, and by linear regression analysis. Normal limits for the percentage of LV filling during rapid diastolic filling and during atrial systole were defined by the 95% confidence limits obtained in normal volunteers (mean ± 2 standard deviations).

Results

Normal data: LV ejection fraction, peak LV filling rate, and time to peak filling rate in normal volunteers (Table I) were within the previously defined normal range for our laboratory.[7] Peak filling rate ranged from 2.5 to 5.0 EDV/s and time to peak filling rate from 88 to 180 ms. LV filling volume during rapid diastolic filling ranged from 69 to 97% of the LV stroke volume (mean 83 ± 7% [SD]), and filling volume during atrial systole ranged from 0 to 31% of stroke volume (mean 16 ± 8%). The 2 mean values do not total 100% because of the small contribution of slow diastolic filling to LV filling volume. On the basis of the distribution of these normal data, the lower limit of normal (95% confidence limit) for filling volume during rapid diastolic filling was 69%, and the upper limit of normal for filling volume during atrial systole was 31% (Fig. 3). The peak rate of filling during rapid diastolic filling did not correlate with the filling volume during either rapid diastolic filling ($r = 0.35$) or atrial systole ($r = 0.51$).

TABLE I Radionuclide Variables Describing Left Ventricular Diastolic Filling

	Normal Volunteers (n = 30)	Hypertrophic Cardiomyopathy (n = 42)		
		Control	Verapamil	p
Heart rate (beats/min)	68 ± 8	71 ± 12	67 ± 9	<0.01
LV ejection fraction (%)	55 ± 6	75 ± 10*	74 ± 10*	NS
LV diastolic filling				
Peak LV filling rate (EDV/s)	3.3 ± 0.6	3.3 ± 1.1	4.2 ± 1.2*	<0.001
Time to peak LV filling rate (ms)	139 ± 25	177 ± 38*	164 ± 24*	<0.01
LV filling volume during RDF (%)	83 ± 7	67 ± 17*	83 ± 7	<0.001
LV filling volume during AS (%)	16 ± 8	31 ± 18*	16 ± 9	<0.001

Data are means ± standard deviation.
AS = atrial systole; EDV = end-diastolic volume; LV = left ventricular; NS = not significant; RDF = rapid diastolic filling.
Statistical significance compared with normal volunteers: * p <0.001.

The contribution of atrial systole to LV filling in normal volunteers is in close agreement with the contrast angiographic data of Hammermeister and Warbasse[19] and the echocardiographic data of Decoodt et al,[20] in which the mean normal contribution of atrial systole to the LV stroke volume was 16%.

Hypertrophic cardiomyopathy: *Control data:* LV ejection fraction in the 42 patients with HC ranged from 50 to 98% (mean 75 ± 10%) and was above the upper limit of normal (72%) in 29 patients. Peak LV filling rate ranged from 1.0 to 6.2 EDV/s and was within the normal range (≥2.5 EDV/s) in 34 patients. Hence, peak filling rate was not different in normal patients and those with HC (Table I). However, the contribution to LV filling volume by rapid diastolic filling (range 8 to 92%) was diminished in patients with HC and the contribution of atrial systole (range 5 to 89%) was increased (Table I, Fig. 3). LV filling during atrial systole was above the upper limit of normal of 31% in 17 patients (40%), including 13 patients whose peak filling rate was in the normal range (Fig. 4 and 5). Neither filling volume during rapid diastolic filling nor filling volume during atrial systole correlated with peak filling rate (r = 0.56 and 0.52, respectively). As previously reported,[7] time to peak filling rate in patients with HC (177 ± 38 ms) was significantly greater than normal (Table I) and was above the upper limit of normal of 180 ms in 24 patients (57%).

Effect of verapamil: Verapamil significantly reduced resting heart rate (Table I). Systolic blood pressure was reduced by verapamil (114 ± 25 mm Hg control, 109 ± 20 mm Hg with verapamil; p <0.05), but diastolic blood pressure was not altered (70 ± 12 mm Hg control, 66 ± 11 mm Hg with verapamil, difference not significant). LV ejection fraction was not changed by verapamil, but peak filling rate significantly increased and time to peak filling rate decreased (Table I), as previously described.[7]

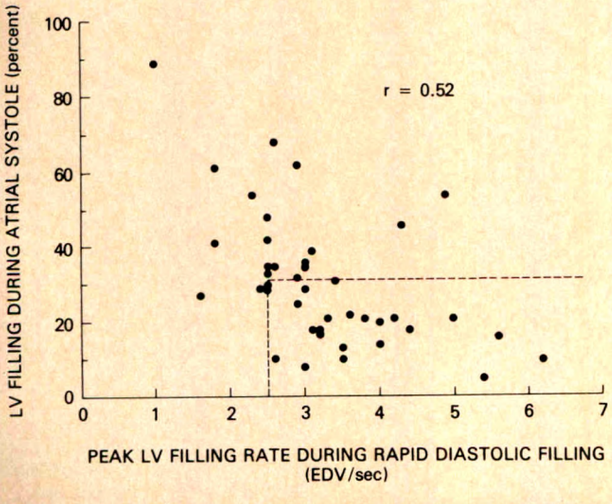

FIGURE 4. Left ventricular (LV) filling volume during atrial systole plotted as a function of peak rate of rapid diastolic filling. **Dashed lines** indicate the expected normal range. LV filling during atrial systole was above normal in 13 patients with normal peak LV filling rate.

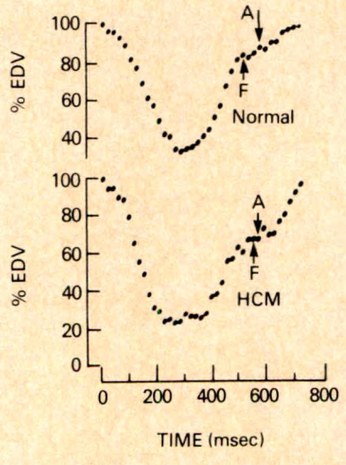

FIGURE 5. Left ventricular time-activity curves from a normal volunteer (**top**) and a patient with hypertrophic cardiomyopathy (HCM). Termination of rapid diastolic filling (F) and onset of atrial systole (A) are indicated. Heart rate (83 and 81 beats/min) and ejection fraction (68 and 73%) are similar. Peak rate of rapid diastolic filling is normal in each patient (4.4 and 3.1 EDV/s), but filling volume during rapid filling is reduced in the patient with hypertrophic cardiomyopathy (76 versus 61%) and filling volume during atrial systole is increased (18 versus 39%). EDV = end-diastolic volume.

TABLE II Variability of Radionuclide Measurements in 25 Patients

	Study I (Mean ± SD)	Study II (Mean ± SD)	Maximal Change Between Studies	Average Change Between Studies (Mean ± SD)
Heart rate (beats/min)	73 ± 12	72 ± 12	12	−0.9 ± 3.8
LV ejection fraction (%)	72 ± 11	72 ± 10	7	0.2 ± 2.4
LV diastolic filling				
Peak LV filling rate (EDV/s)	2.8 ± 1.1	2.9 ± 1.1	0.7	0.2 ± 0.23
Time to peak LV filling rate (ms)	192 ± 46	187 ± 42	56	−5.2 ± 24
LV filling volume during RDF (%)	66 ± 11	66 ± 12	11	0.1 ± 5.5
LV filling volume during AS (%)	38 ± 17	36 ± 17	12	−1.8 ± 4.9

SD = standard deviation. For other abbreviations, see Table I.

This change was associated with an increase in the contribution of rapid diastolic filling to LV filling volume, from 67 ± 17% to 83 ± 7% ($p < 0.001$), and a decrease in the contribution of atrial systole to LV filling, from 31 ± 18% to 16 ± 9% ($p < 0.001$) after verapamil (Table I, Fig. 6 and 7). LV filling volume during rapid diastolic filling was subnormal after verapamil in only 2 patients (5%), and filling volume during atrial systole was above normal in only 3 patients (7%).

Reproducibility of radionuclide measurements: In the 25 patients with HC who were studied twice with no medications, none of the variables describing LV diastolic filling changed between the 2 studies (Table II). The variations in ejection fraction, peak filling rate, and time to peak filling rate were similar to the error previously described for these parameters.[7] The average change between studies was 0.1 ± 5.5% for the percentage of filling volume during rapid diastolic filling and 1.8 ± 4.9% for the percentage of filling during atrial systole. Thus, in most patients (as well as in mean values), the changes induced by verapamil in relative filling during rapid filling and atrial systole were >2 standard deviations above the expected variability of the technique (Fig. 6). The correlation between study 1 and study 2 was $r = 0.96$ (SE = 5.05) for filling volume during rapid diastolic filling and $r = 0.89$ (SE = 5.16) for filling volume during atrial systole.

Discussion

Impaired diastolic filling of the hypertrophied left ventricle is a common manifestation of patients with HC[1,3–7] that contributes to the production of symptoms of pulmonary venous hypertension, reduced cardiac output, and possibly angina pectoris. Previous studies indicate that the timing of rapid diastolic filling is abnormal in such patients,[4,6,7] although the peak rate of rapid diastolic filling may be normal.[7] Despite the normal rate of rapid diastolic filling, our data indicate that the proportion of LV filling during rapid diastolic filling is reduced. Because LV stroke volume is directly related to LV end-diastolic volume in patients with HC,[21] reduced LV filling during early rapid diastolic filling would decrease LV end-diastolic volume and forward cardiac output, unless the contribution to LV filling by slow diastolic filling or atrial systole was augmented. In the current study, the percentage of LV filling during atrial systole in patients with HC was significantly greater than that in normal subjects. The contribution of atrial systole to LV filling was above the upper limit of normal in 40% of patients, including 36% of patients whose peak rate of rapid diastolic filling was within the normal range. These data support earlier echocardiographic observations that the volume of LV filling during rapid diastolic filling is reduced in such patients and that of atrial systole is increased.[6]

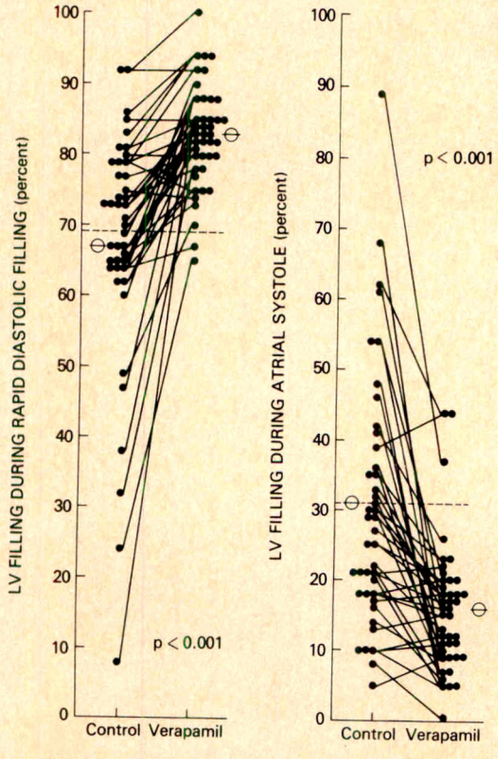

FIGURE 6. Left ventricular (LV) filling volume during rapid diastolic filling (**left**) and during atrial systole (**right**) before and after verapamil. Filling volumes are expressed as percent of LV stroke volume. **Dashed lines** indicate the lower limit of normal for filling during rapid diastolic filling (69%) and the upper limit of normal for filling during atrial systole (31%). **Open circles with bars** indicate mean values.

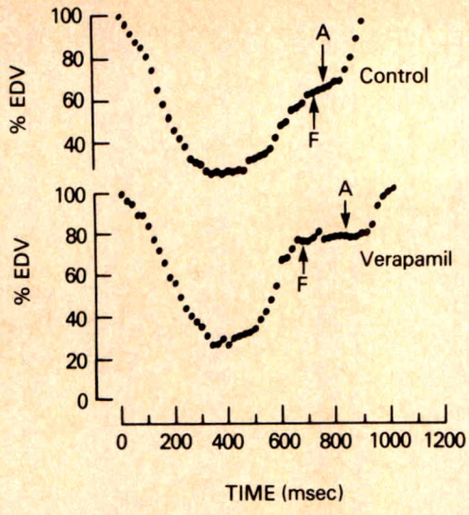

FIGURE 7. Time-activity curves obtained from a patient with hypertrophic cardiomyopathy before (control) and after verapamil. Ejection fraction was not significantly affected (75 to 72%). Increased rate of rapid diastolic filling after verapamil (from 1.8 to 3.4 EDV/s) is associated with increased contribution of rapid filling to ventricular filling volume (from 49 to 71%) and reduced contribution of atrial systole (from 41 to 26%). Termination of rapid filling (F) and onset of atrial systole (A) are indicated. EDV = end-diastolic volume.

Verapamil therapy reduces the time period of isovolumic relaxation and increases the time period of rapid diastolic filling.[11] The rate of rapid diastolic filling is increased by verapamil and the time from end-systole to the peak rate of rapid filling is decreased.[7] The results of the current investigation indicate that these changes are associated with a significant increase and, in many cases, normalization of the contribution of rapid diastolic filling to LV diastolic volume and a reduction in the contribution of atrial systole (Fig. 6 and 7).

In the absence of quantitative estimates of absolute LV volume (a limitation of our noninvasive technique), the abnormalities in LV filling during rapid filling and atrial systole, and the changes induced by verapamil, cannot be measured volumetrically and must be expressed relative to total stroke volume. However, previous studies of patients with HC indicate that intravenous administration of verapamil results in either no change or an increase in total stroke volume.[11,21,22] If these intravenous data pertain to the effects of oral verapamil therapy, then the changes we observed after verapamil in relative LV filling during the 2 phases of diastole would represent an increase in absolute LV volume contributed by rapid diastolic filling.

Our data have several potential clinical implications. Increased dependence on atrial systole to maintain adequate LV filling volumes for preservation of cardiac output places many patients with HC at risk of acute reduction in cardiac output with the loss of synchronized atrial contraction. Hence, atrial fibrillation, atrial flutter, and ventricular tachycardia, commonly encountered arrhythmias in these patients,[8–10] may precipitate acute, life-threatening hemodynamic decompensation. By increasing the relative magnitude of LV filling volume during early rapid diastolic filling and thereby diminishing the relative filling contribution of atrial systole, verapamil therapy may reduce the hemodynamic risks of any arrhythmia leading to the loss of the atrial contribution to LV filling.

Regression of Myocardial Cellular Hypertrophy With Vasodilator Therapy in Chronic Congestive Heart Failure Associated With Idiopathic Dilated Cardiomyopathy

DONALD V. UNVERFERTH, MD, JOHN P. MEHEGAN, MD, RAYMOND D. MAGORIEN, MD, BARBARA J. UNVERFERTH, MS, and CARL V. LEIER, MD

Forty-nine patients with idiopathic dilated cardiomyopathy (IDC) were evaluated to determine the hemodynamic and morphologic effects of vasodilator therapy. Hydralazine (225 mg/day, H), isosorbide dinitrate (160 mg/day, I), and combination H + I therapy were compared with placebo (P) at baseline and after 3 months of continuous therapy. Thirty-three randomly assigned patients completed the study. Hemodynamic parameters included the echocardiographic percent change of left ventricular diameter (%ΔD), the systolic time intervals ratio of preejection period to left ventricular ejection time (PEP/LVET), the pulmonary capillary wedge pressure, mean pulmonary artery pressure, cardiac index, systemic vascular resistance, and pulmonary vascular resistance. An endomyocardial biopsy was performed at baseline and after 3 months; the myocardial cell diameter of 50 cells per biopsy was measured.

During the 3-month study 5 patients died; there was not a significant difference among the groups in the number of deaths. The %ΔD and PEP/LVET did not change in the P or I groups but did improve significantly from baseline in the H and H + I groups. The pulmonary capillary wedge and mean pulmonary artery pressures and the pulmonary vascular resistance did not change in the P or H groups but did decrease significantly in the I and H + I groups. The P and I groups did not have improvement in systemic vascular resistance or cardiac index, whereas the H group had a decrease in systemic vascular resistance and an increase in cardiac index from 2.5 ± 0.4 to 3.1 ± 0.4 liters/min/m² ($p < 0.05$). The H + I group also had a decrease in systemic vascular resistance; the cardiac index increased from 2.3 ± 0.4 to 3.1 ± 0.4 liters/min/m² ($p < 0.01$). Myocardial cell diameter did not change in the P or I group. Cell diameter of the H group decreased from 25.4 ± 3.1 μm at baseline to 23.1 ± 3.8 μm ($p < 0.05$) after 3 months of continuous therapy. The H + I group decreased its cell diameter from 23.9 ± 3.7 to 22.2 ± 2.2 μm ($p < 0.05$).

Compared with P and H, patients treated with I alone or H + I had a significant reduction of preload. In contrast to P and I, H alone and H + I elicited improvement in parameters of inotropy and afterload, and this improvement was accompanied by a reduction in cell diameter. Chronic therapy of heart failure with H and H + I effects a persistent augmentation of cardiac function and improvement of myocardial cellular morphology.

Vasodilator therapy is now an accepted method of managing patients who have congestive heart failure that remains refractory to digitalis and diuretics.[1–3] Such congestive heart failure is usually characterized by an elevated preload or afterload, or both; a popular vasodilator regimen employs isosorbide dinitrate (a preload-reducing agent) or hydralazine (an afterload-reducing agent), or both.[4] Although this combination improves resting hemodynamic function[4,5] and augments exercise performance both immediately[6–9] and during long-term therapy,[10–12] its effect on myocardial morphology has not been studied. This study assesses the effects of oral isosorbide dinitrate, hydralazine, and the combination of the 2 on the myocardial cell size of patients with chronic, severe congestive heart failure secondary to idiopathic dilated cardiomyopathy (IDC).

Methods

Patients eligible for this study had diagnostic catheterization for determination of pressures, function, and coronary anatomy. Qualifying characteristics of the patients for the

study included left ventricular end-diastolic pressure >10 mm Hg, an angiographic ejection fraction <50%, and no narrowings >50% in diameter in any coronary artery. Exclusion criteria included an alcohol intake >1 drink per day over the 2 months before study and myocarditis by endomyocardial biopsy.

Forty-nine subjects, 37 men and 12 women, entered the study. The average age was 57 ± 10 years (mean ± standard deviation [SD]). The symptoms of this group included dyspnea on exertion in all 49, easy fatigability in 10, peripheral edema in 9, angina-like chest pain in 10, and palpitations in 6. Duration of symptoms ranged from 1 to 120 months. Three were classified as New York Heart Association functional class II, 34 as functional class III, and 12 as functional class IV. The catheterization data revealed an average angiographic ejection fraction of 27 ± 9%, the average cardiac index was 2.4 ± 0.6 liters/min/m^2, and the average pulmonary capillary wedge pressure was 21 ± 8 mm Hg. Twenty-six patients had some degree of mitral regurgitation; 6 had tricuspid regurgitation. The cause of the congestive cardiomyopathy included an idiopathic etiology in 31, remote alcohol abuse in 16, and cardiomyopathy associated with the peripartal period and family history in 1 each. All patients were on maintenance doses of digitalis and diuretics; antiarrhythmic and anticoagulant medications were employed when indicated. The digitalis, diuretic, and antiarrhythmic medications were maintained at the same dosage level over the 3 months of the study.

Invasive and noninvasive testing: All patients had endomyocardial biopsy through the right internal jugular vein.[13] The tissue removed from the right side of the interventricular septum was immediately submerged in cold 2% glutaraldehyde and reserved for analysis. The internal jugular site was then used for placement of a triple-lumen, flow-directed catheter positioned in the pulmonary artery. This catheter provided measurement of the pulmonary artery and pulmonary capillary wedge pressures and cardiac output; pressures were determined with Electronics for Medicine M2101 pressure amplification units and cardiac outputs by thermodilution using an Instrumentation Laboratory 601 computer and 602 recorder. Systemic blood pressure was recorded indirectly with a calibrated sphygmomanometer. Systemic vascular resistance was calculated from the formula: systemic vascular resistance = mean systemic arterial pressure × 80/cardiac output. Pulmonary vascular resistance was obtained by the formula: pulmonary vascular resistance = mean pulmonary artery pressure × 80/cardiac output.

Echocardiograms were performed with an Echo IV ultrasonoscope and an Electronics for Medicine recorder. A single echocardiographic technician performed echocardiography using identical techniques and transducer placement for each study. Blinded echocardiographic interpretation was performed by 1 of us (DVU) in accordance with the recommendations of the American Society of Echocardiography.[14] The fractional shortening of the minor axis of the left ventricle with systole (%ΔD) was used as the echocardiographic determinant of left ventricular function. Systolic time intervals were obtained with an Electronics for Medicine unit using the specifications previously outlined.[15] The preejection period (PEP) to left ventricular ejection time (LVET) ratio was used as the measure of left ventricular performance. A single technician was used to perform this test. The reproducibility of these tests has previously been determined in our laboratory.[16]

Drug testing: Measurements included systemic blood pressure, heart rate, pulmonary artery pressure, pulmonary capillary wedge pressure, systemic vascular resistance, pulmonary vascular resistance, cardiac output, echocardiographic %ΔD, and the systolic time intervals PEP/LVET. Measurements were made at baseline and repeated 30 minutes and 1, 2, 3, 4, and 5 hours after drug administration. Oral isosorbide dinitrate (I) (40 mg), oral hydralazine (H) (1 mg/kg), or a combination of the 2 (H + I) was administered on successive days to establish that no adverse reaction would occur with these drug regimens. The patients were then randomly assigned to 1 of 4 treatment groups. The first group received placebo (P) (4 times a day), the second group received I (160 mg/day in 4 divided doses), the third group received H (3 mg/kg/day in 3 divided doses), and the last group received a combination of H + I in the same doses just mentioned. Patients were blinded to their treatment group.

Follow-up studies: Patients returned monthly in the ensuing 3 months for clinical evaluation and pill counts. After 3 months of therapy, the patients were readmitted and underwent repeat endomyocardial biopsy and repositioning of the triple-lumen, flow-directed catheter. The patients had repeat hemodynamic and noninvasive tests 30 minutes and 1, 2, 3, 4, and 5 hours after taking their assigned drug regimen (P, I, H, or H + I).

Analysis of biopsy tissue: This laboratory has performed over 600 endomyocardial biopsy procedures. At least 2 pieces of tissue from each procedure are reserved for histologic analysis. Various fixative and staining procedures have been used to determine which technique presents the least artifact. In our laboratory, the best histologic preservation and the most reproducible results occur when the tissue is >1 mm^3 and immediately placed in cold buffered 2% glutaraldehyde. This finding is similar to that of Thomsen and Torp[17] but differs from the recommendation of Fenoglio.[18] The tissue is kept in buffered glutaraldehyde for precisely 4 hours after which it is transferred to phosphate buffer.

The tissue from each biopsy procedure in this study measured 1 to 2 mm^3 and weighed 1 to 4 mg. Tissue was placed in 2% buffered glutaraldehyde (pH 7.35) within 12 seconds of closure of the jaws of the bioptome on the right ventricular septal myocardium. Light microscopic slides 3 to 5 μm in thickness were prepared from paraffin-embedded sections. The slides were stained by routine hematoxylin and eosin by the method of Sheehan and Hrapchak.[19] The myocardial slices were examined through a 43× objective lens and a 10× eyepiece with an ocular micrometer disc. The diameter of a myocardial cell was determined by measuring the distance across the cell at its most narrow plane across the nucleus (Fig. 1) according to the technique previously described by Baandrup and Olsen[20] and as previously reported by our laboratory. At least 50 cells from each biopsy were measured and their diameters averaged to determine the value for each patient.

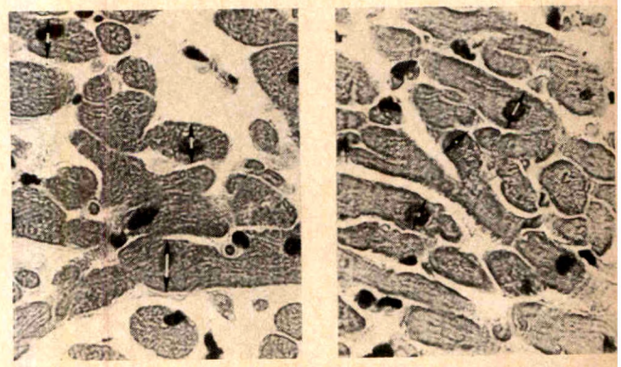

FIGURE 1. Hematoxylin and eosin stain of endomyocardial biopsy specimens from a patient who received hydralazine and isosorbide dinitrate. **Left,** pretreatment biopsy; **right,** after 3 months of therapy. (Magnification ×450, reduced 43%.)

The microscopist was blinded to the treatment group and to the time of the biopsy. The difference of the means on repeated measurements of the biopsies was <5%.

Analysis of data: The peak effect of the patients' drug regimen after 3 months of therapy was compared with the average baseline measurements before the start of the study by the paired *t* test. The myocardial cell size in each group was compared from the baseline to that at 3 months of therapy by the paired *t* test. The change in each of these tests from baseline was compared between the groups by unpaired Student's *t* test. In addition, linear regression analysis was used to correlate changes in individual and group myocardial cellular diameters with changes in pulmonary capillary wedge pressure, cardiac index, systemic vascular resistance, and pulmonary vascular resistance.

Results

After 3 months of continuous treatment, 33 patients returned for follow-up study. Sixteen patients did not complete the study because of death in 5 patients, resumption of alcohol use in 2, change of residence in 3, technical problems with biopsy or catheter in 1, and refusal to repeat study in 5. The deaths by group were P, 0 deaths; I, 3; H, 1; and H + I, 1 (difference among groups not significant [NS]). Four of the 5 deaths were sudden, presumably from arrhythmias, although none of these was documented by monitoring at the time of death. One patient died from pneumonia at her local hospital. No patient withdrew from the study because of intolerable side effects, although several patients complained of severe headaches early in the study which dissipated with time.

The 33 patients who completed the study were assigned to the following groups: P, 11 patients; I, 6; H, 9; and H + H, 7. Table I shows the baseline and post-therapy value for the 33 subjects who completed the study. The baseline mean ± 1 SD is tabulated for each

B = baseline; Cell D = cell diameter (μm); FC = functional class; P-Tx = observations after 3 months of continuous therapy; PCW = pulmonary capillary wedge pressure (mm Hg); PEP/LVET = preejection period to left ventricular ejection time by systolic time intervals; SD = standard deviation; TI = technical inadequate echocardiogram; %ΔD = percent change of the minor axis of the left ventricle with systole by echocardiography.

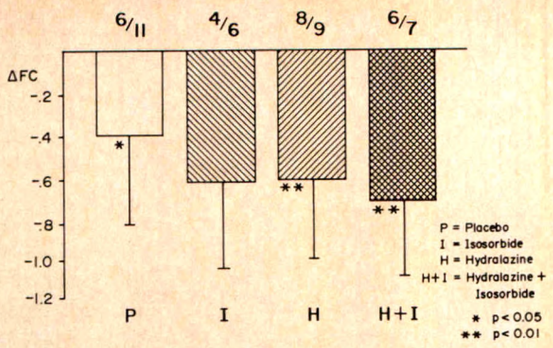

FIGURE 2. Mean change ± SD in functional class (ΔFC) from baseline to 3 months of therapy for each group. All 4 groups reported significant improvement. The fractions at the top represent the number of patients improved over the total number in that group who completed the study.

test for each group. No significant differences existed at baseline among the groups for any of these characteristics.

After 3 months of continuous therapy and while still on therapy, a significant improvement in functional class was noted in all groups (Fig. 2). Improvement was noted in 6 of the 11 patients receiving P, in 4 of 6 receiving I, in 8 of 9 receiving H, and in 6 of 7 receiving H + I.

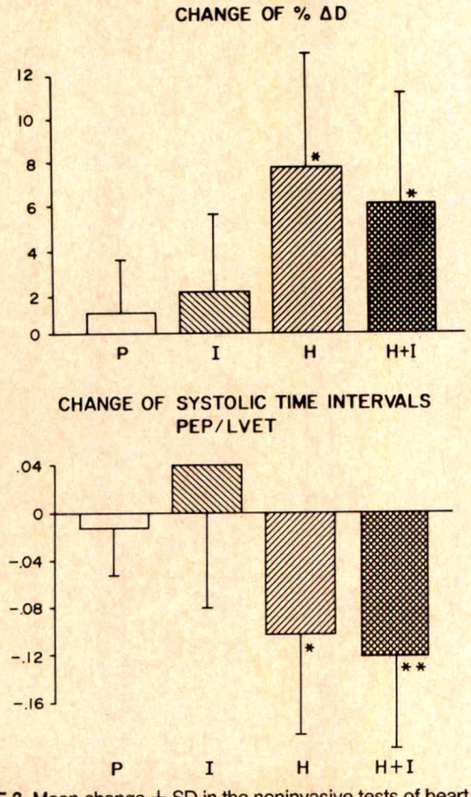

FIGURE 3. Mean change ± SD in the noninvasive tests of heart function for each group. The H and H + I groups had an improved % ΔD (* $p < 0.05$) from baseline to 3 months of therapy. The H and H + I groups also had improvement in the preejection period to left ventricular ejection time ratio (PEP/LVET) of the systolic time intervals (* $p < 0.05$, ** $p < 0.01$).

The change from baseline of the noninvasive tests of left ventricular function is shown in Figure 3. The %ΔD did not change in the P or I group, but did improve from 16 ± 5% ($\bar{X}$ ± SD) to 23 ± 6% ($p < 0.05$) in the H group and from 14 ± 2% to 19 ± 4% ($p < 0.05$) in the H + I group. The PEP/LVET also did not change in the P or I group. The H group had a decrease in PEP/LVET from 0.67 ± 0.12 to 0.57 ± 0.09 ($p < 0.05$). The H + I group had a decrease in PEP/LVET from 0.69 ± 0.09

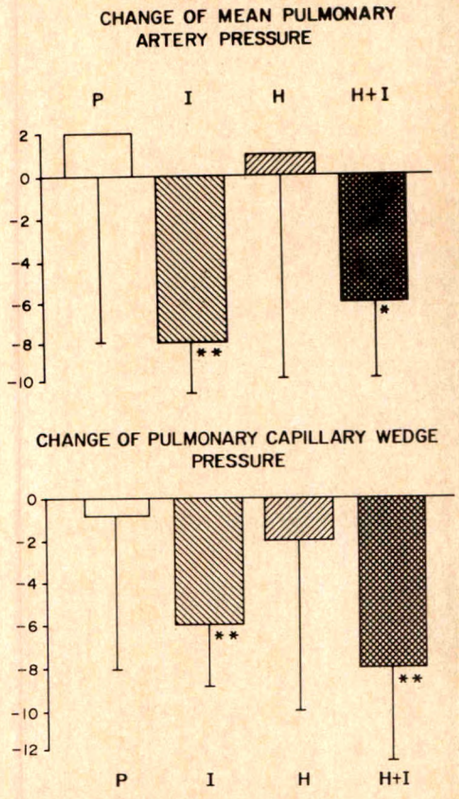

FIGURE 4. The **vertical axis** shows the mean change (mm Hg) ± standard deviation from baseline to 3 months of therapy for each group. The I and H + I groups had a significant decrease in mean pulmonary artery pressure and pulmonary capillary wedge pressure (* $p < 0.05$, ** $p < 0.01$), whereas the P and H groups did not change.

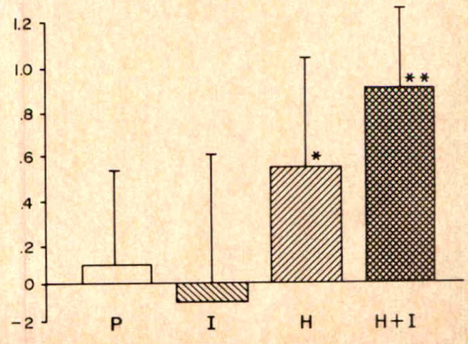

FIGURE 5. The **vertical axis** shows the change in cardiac index (in liters/min/m^2) from baseline. The P and I groups demonstrated no change. The H and H + I groups had an increase in cardiac index (* $p < 0.05$, ** $p < 0.01$).

to 0.58 ± 0.13 ($p < 0.01$). There was no difference among the groups for the changes from baseline in either %ΔD or PEP/LVET.

Changes in mean pulmonary artery and pulmonary capillary wedge pressures are shown in Figure 4. Neither pulmonary artery nor pulmonary capillary wedge pressure changed from baseline in the P or H group. The I group had a decrease in mean pulmonary artery pressure from 28 ± 9 mm Hg at baseline to 20 ± 9 mm Hg ($p < 0.01$) during treatment and in pulmonary capillary wedge pressure from 19 ± 9 to 13 ± 7 mm Hg ($p < 0.01$). The H + I group also demonstrated a significant decrease in mean pulmonary artery pressure from 33 ± 4 to 27 ± 4 mm Hg ($p < 0.05$) and in pulmonary capillary wedge pressure from 23 ± 5 to 16 ± 4 mm Hg ($p < 0.01$). There was no significant difference among the groups in these changes.

The change in cardiac index from baseline is shown in Figure 5. Neither the P nor the I group demonstrated an improvement in cardiac index, whereas the H and H + I groups did. The H group had an increase in cardiac index from 2.5 ± 0.4 to 3.1 ± 0.4 liters/min/m^2 ($p < 0.05$). The H + I group had an increase in cardiac index from 2.3 ± 0.4 to 3.1 ± 0.4 liters/min/m^2 ($p < 0.01$). There was no significant difference between the groups in these changes.

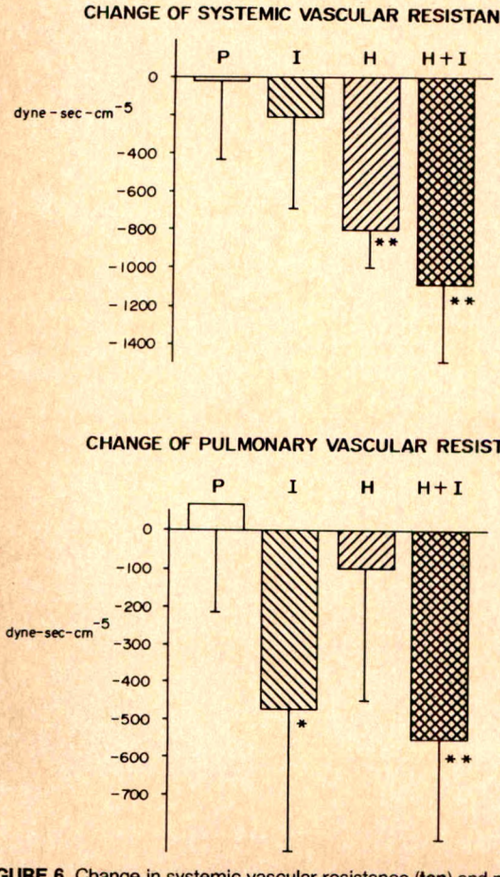

FIGURE 6. Change in systemic vascular resistance (**top**) and pulmonary vascular resistance (**bottom**) from baseline to after 3 months of therapy (* $p < 0.05$, ** $p < 0.01$).

Changes in vascular resistance from baseline are shown in Figure 6. There was no significant difference among the groups at baseline for the systemic or pulmonary vascular resistances. The P group did not have a change in systemic or pulmonary vascular resistance. The I group did not have a change in systemic vascular resistance from baseline; however, its pulmonary vascular resistance decreased from 691 ± 423 dynes s cm^{-5} at baseline to 308 ± 213 dynes s cm^{-5} ($p < 0.05$) after 3 months of therapy. The H group did not have a change in pulmonary vascular resistance, but the systemic vascular resistance decreased from 2,084 ± 484 to 1,442 ± 424 dynes s cm^{-5} ($p < 0.01$). Both systemic vascular resistance (2,235 ± 445 to 1,360 ± 306 dynes s cm^{-5}, $p < 0.01$) and pulmonary vascular resistance (723 ± 236 to 297 ± 131 dynes s cm^{-5}, $p < 0.01$) decreased in the H + I group.

Myocardial cell diameter (Fig. 7) did not change in the P or I group. Cell diameter in the H group decreased from 25.4 ± 3.1 μm at baseline to 23.1 ± 3.8 μm ($p < 0.01$) after 3 months of continuous therapy. The H + I group had a decrease in cell diameter from 23.9 ± 3.7 to 22.2 ± 2.2 μm ($p < 0.05$). There was no significant difference between the groups in these changes.

Changes in myocardial cell diameter in individual patients did not correlate with changes in pulmonary capillary wedge pressure, cardiac index, systemic vascular resistance, or pulmonary vascular resistance. There was a correlation of the changes in cell diameter of group means with cardiac index ($r = 0.86$) and systemic vascular resistance ($r = 0.87$). The change in cell diameter did not correlate with changes in pulmonary capillary wedge pressure or pulmonary vascular resistance.

Discussion

Clinical response: This study demonstrated that I-containing drug regimens resulted in a persistent decrease in preload as shown by the decreased pulmonary capillary wedge pressure. Hydralazine-containing regimens resulted in a persistent improvement in systolic function as demonstrated by an improved echocardiographic %ΔD, systolic time intervals PEP/LVET, and cardiac index. In addition, symptomatic improvement was impressive. Not only did treated patients feel better, but 6 of 11 patients receiving placebo reported

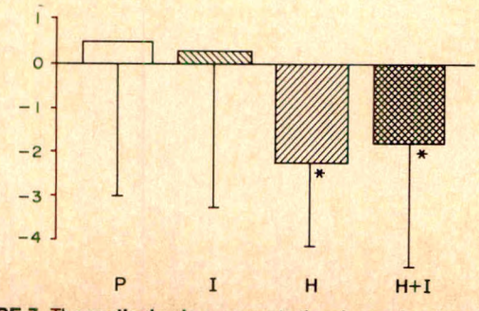

FIGURE 7. The **vertical axis** represents the change in micrometers of the myocardial cell diameter from baseline to 3 months of therapy. The decrease in cell size was significant in the H and H + I groups.

some functional improvement despite an absence in hemodynamic response. Improved functional class in the placebo group may reflect significant motivational factors or subtle changes in general care, or both, with close follow-up over the 3-month period.

Tolerance: Significant diminution in response with chronic therapy (tolerance) did not develop with either agent. Tolerance to I is controversial.[22–24] Thadani et al[22] showed that plasma I levels are not decreased during chronic therapy but that end-organ responsiveness is decreased. Lee et al[24] demonstrated that resting and exercise hemodynamic response in their patients was maintained 1 month. A loss of responsiveness to I after 3 months of therapy was not observed in our study.

A long-term H study has demonstrated tolerance to this agent in 11% of patients after an average of 37 weeks of therapy.[25] The patient group displaying H tolerance retained responsiveness to intravenous nitroprusside and other oral vasodilators.[25] Of the 16 patients on H or H + I who completed our 3-month study, all demonstrated continued hemodynamic responsiveness. Therefore, resting invasive and noninvasive tests did not demonstrate tolerance to I or H in this study.

Deaths: Five patients died during the 3-month course of study, 4 from sudden death and 1 from pneumonia. One patient who died suddenly showed no evidence of emboli on postmortem examination. He presumably died from an arrhythmia. Sudden death is consistent with previous reports which suggest that cardiomyopathic patients die more commonly from arrhythmias and emboli than from refractory heart failure.[26–29] The 4 sudden deaths were divided among the 3 treatment groups; no deaths occurred in the placebo group. Statistical significance was not achieved for the incidence of death among the groups.

Measurements of myocardial cell size: The unique aspect of this study was the documentation that myocardial cell size decreased with therapy. However, several problems interfere with the interpretation of these results. The techniques employed for cell sizing have been studied in our laboratory and the present methods appear to be best suited for our purposes. The techniques are precisely replicated with each biopsy and the reproducibility has been documented (<5% error on repeated measures). However, it is impossible to determine how closely our measurements mimic in vivo cell diameter.

A second problem is that of right versus left heart biopsy. The tissue for this study was removed from the right side of the interventricular septum and yet the changes in cell size correlated with the changes in systemic vascular resistance ($r = 0.87$) and not pulmonary vascular resistance ($r = 0.18$). A previous study demonstrated the similarity of cellular morphology of biopsy specimens from the left and right ventricle.[20] However, that study did not include quantitative cell sizing. Our study cannot resolve the question of the pertinence of left versus right heart biopsy, but it would appear that right ventricular endomyocardial biopsies are sufficient to explore some important morphologic changes in IDC.

Regression of hypertrophy: The myocardial cell diameter of the study patients was 23.2 ± 2.6 μm at baseline (normal 16 to 20 μm, unpublished observation from our laboratory). Animal models clearly demonstrated that hypertrophy is associated with increased afterload,[30] increased preload,[31] and intermittent hypoxia.[32] All 3 factors may have played a role in inducing cell growth in the study patients. Increased preload and afterload were documented at catheterization, and coronary blood flow studies in similar patients demonstrated decreased flow per gram of myocardium.[33,34]

Hypertrophy regressed toward normal groups that had H as part of their therapy. Reduction of a pressure load in animal models (release of an aortic band)[35] and in human subjects (aortic valve replacement for aortic valve disease[36] or treatment of hypertension)[37] leads to a regression of hypertrophy. Hydralazine not only reduces afterload but also increases coronary blood flow to a greater degree than the increase in myocardial oxygen demand.[38] Thus, H may have been successful in reducing cell size for these reasons.

The decrease in myocardial cell size is potentially important because (1) hypertrophied myocardial cells have depressed contractility, and (2) hypertrophied myocardium is less efficient. Factors that determine the course of hypertrophy and its effect on contractility are a combination of: the degree of wall stress, the duration of stress, the nature of the inciting stimulus, and the age and health of the subject.[39,40] A gradual progression in hypertrophy in a young animal does not depress contractility.[41] Sudden stress of a load on an older ventricle leads to pathologic hypertrophy and a depression of contractility.[39,42] Depressed contractility may be due at least partially to decreased enzyme activity, especially myosin ATPase.[43–47]

The hypertrophied myocardium is less efficient. With hypertrophy the intercapillary distance increases[48] and the capillary density decreases[49] with a resultant relative hypoxia of parts of the cell.[50] Within the cell, the mitochondrial to myofibrillar ratio decreases[51,52] and the ATP concentration decreases.[53] In addition, for each ATP consumed there is less tension produced.[54] Thus, the hypertrophied myocardium is unable to fully oxygenate its cells, less ATP is produced, and less force is generated.

The regression of hypertrophy is potentially beneficial to the patient by the reduction in intercapillary distance and the increase in capillary density. Some abnormalities of the myocardial cells are reversed (such as RNA content); others are not (hydroxyproline content).[35] Whether these improvements will be translated into long-term improved myocardial function or decreased mortality has not been determined. Further experience with vasodilators and long-term studies may help answer these questions.

Acknowledgment: We would like to thank George Rieser, Jan Kish, Pam Newton, and Dawn Orth for their technical assistance and Tami West for the preparation of the manuscript.

Makes hemodynamic sense in the treatment of hypertension

Reduces blood pressure

It's as effective as propranolol in normalizing blood pressure (dbp ≤ 90 mmHg) when used alone. It's also effective when used in combination with a diuretic.[1]

Has little effect on resting cardiac output

Unlike other beta blockers, Visken (pindolol) maintains resting cardiac output during long-term therapy. The clinical significance of this has not been evaluated.

Reduces total peripheral resistance*

Visken (pindolol) reduces one of the recognized components of hypertension: increased peripheral resistance.* Studies of 178 patients treated with Visken (pindolol) for at least two weeks have shown that Visken therapy reduces total peripheral resistance.[1]

Reduces exercise-induced tachycardia

Like other beta blockers, Visken (pindolol) blocks stimulation by catecholamines to reduce exercise-induced increases in systolic blood pressure and heart rate.

raphy.[5,10,11] The cause of this disparity is speculative; however, it may represent a loss in sensitivity of edge detection caused by the lesser density differential between the diluted opacified blood nearest the endocardium in comparison with the soft tissue density of myocardial muscle. It is possible that this can be overcome by utilizing densitometric techniques and automated edge detection techniques.[13,14]

One of the major adverse reactions to contrast medium given intravascularly (or intracardiac) is arrhythmias.[15–18] The patients deemed most at risk in these noncontrolled studies are older male patients who were presumed to have coronary artery disease. Indeed, arrhythmias are not infrequent in patients with coronary artery disease undergoing left ventriculography and coronary angiography.[19]

In the current study, the incidence of ventricular ectopy was smaller after digital intravenous angiography than after direct left ventriculography. The absence of ventricular ectopy with the digital technique may be in part due to mechanical factors: the recoil of the left ventricular catheter serves as an endocardial irritant. An additional advantage of digital intravenous angiography is homogeneous opacification of the ventricle compared with the streaming of contrast medium with poor mixing inherent in direct left ventriculography. Regardless of electrophysiologic concerns, the absence of ventricular ectopic beats during peak left ventricular opacification decreases the possibility of a study on which quantitative analysis is precluded.

Digital subtraction and other contrast enhancement techniques can also be used after pulmonary arterial injection or direct left ventricular injection[10,20] with smaller volumes of contrast medium in order to diminish the hemodynamic and toxic side effects of contrast medium. Adequate visualization of the left ventricle with smaller volumes of contrast medium enables the utilization of multiple injections during the monitoring of physiologic and potential therapeutic interventions.

The important technical factors leading to inadequate digital fluoroscopic studies is motion of background structures in the region-of-interest caused by movement of the patient, respiratory activity, and coughing. In some instances when motion occurred between noncontrast and contrast images, another mask could be formed from fluoroscopy obtained after contrast medium had cleared from the left ventricle. Videotape recording of all fluoroscopic data from several seconds preceding the intravenous injection of contrast medium until contrast media had cleared from the left ventricle provided additional choices for mask images during postprocessing of the data.

In order to digitize the left ventricular images at a high framing rate (30 frames/second), a relatively coarse image matrix was used (128 × 128 pixels). For a large structure such as the left ventricle, this matrix density proved adequate as demonstrated by the good correlation between digital fluoroscopic and direct left ventricular estimates of volumes. On the other hand, adequate resolution of much smaller peripheral vessels containing a considerably lower concentration of contrast medium requires a greater matrix density.[1,2]

Compared with the relatively high radiation dose associated with pulsed X-ray exposures needed for digital fluoroscopy of peripheral vessels,[1,2,4] the technique used for digital intravenous ventriculography involved continuous fluoroscopy with radiation exposures (4.5 to 9.0 mA) only slightly greater than those used for standard fluoroscopy. Moreover, the technique used in the current study whereby fluoroscopic data were recorded on videotape and subsequently digitized into the image processing computer extends these types of studies to remote fluoroscopic facilities such as the coronary care unit.

Digital intravenous ventriculography offers several advantages over direct ventriculography: it provides adequate opacification of the ventricle without arrhythmias during the period of opacification; avoidance of arterial catheterization renders it an outpatient examination; and homogeneous opacification of the ventricle facilitates the application of automated programs for quantitation of segmental left ventricular contraction.

Regional Distribution of Pulmonary Blood Volume: An Index of Pulmonary Capillary Wedge Pressure Determined From Blood Pool Scintigraphy

TIMOTHY M. BATEMAN, MD, RICHARD J. GRAY, MD, LAWRENCE S. C. CZER, MD, RONALD L. LEVY, MD, MORGAN E. STEWART, MS, MICHELE A. DeROBERTIS, RN, DAVID E. BROWN, CNMT, JACK M. MATLOFF, MD, H. J. C. SWAN, MD, PhD, and DANIEL S. BERMAN, MD

Progressive redistribution of pulmonary blood flow to the lung apices occurs with increasing degrees of left ventricular failure, and correlates with increasing pulmonary capillary wedge pressure (PCWP). If similar changes in pulmonary blood volume (PBV) occur, then technetium-99m equilibrium blood pool scintigraphy, by assessing relative distribution of PBV, may allow prediction of PCWP. Therefore 30 patients being monitored with pulmonary artery balloon flotation catheters underwent imaging. PCWP was compared with the average radioactive count density arising from apical (A) and basal (B) regions of interest within the right lung, expressed as an A/B ratio. Correlation was strong for patients imaged erect, either posteriorly (r = 0.864, p = 0.001) or in the 45° left anterior oblique position (r = 0.842, p = 0.001), and only slightly less impressive for patients imaged supine (r = 0.678, p = 0.001). Especially when imaging was performed with patients erect, an A/B ratio greater than unity identified with high sensitivity (100%) and specificity (83 to 88%) an abnormally elevated PCWP (>12 mm Hg). Moreover, directional changes in the A/B ratio reflected concomitant changes in PCWP after intervention. Thus, analysis of lung A/B radioactive count ratios obtained by equilibrium blood pool scintigraphy may be used to evaluate PCWP.

Since the initial description of the assessment of pulmonary capillary wedge pressure (PCWP) by means of a flow directed balloon-tipped catheter,[1] years of clinical application have established the importance of this measurement as an index of cardiac function. Because it reflects left ventricular diastolic pressure, knowledge of PCWP is useful in judging cardiac performance, in guiding and assessing therapy, and in determining prognosis.[2] Measurement has traditionally required a hospital-based invasive procedure that has identified risks, patient discomfort, and considerable expense. A reliable noninvasive evaluation of PCWP is thus needed.

Radionuclide techniques have been used to assess both pulmonary blood flow patterns[3,4] and pulmonary blood volume (PBV).[5] Importantly, it has been shown that pulmonary blood flow is progressively redistributed toward the lung apex as left atrial pressure increases.[4] It has also been shown that PBV increases as left atrial pressure rises,[6,7] and that this increase may not be apportioned equally throughout the pulmonary vascular bed.[8,9] If PBV redistributes as left atrial pressure changes, a technique that measures the relative intravascular volume of lung apex and base should provide an index of PCWP. Technetium-99m equilibrium blood pool scintigraphy is a widely available, simple, low-risk, and rapid procedure that can assess relative distribution of intravascular volume. We therefore designed this study to determine whether knowledge of the relative distribution of technetium-99m labeled red blood cells in the lungs could be used to predict PCWP.

Methods

Patients: Thirty patients (24 men, 6 women) participated in this study. All had undergone open-heart surgery (15 coronary artery bypass graft procedures; 7 mitral valvular replacements; 8 aortic valvular replacements) 2 days before the study, and had in place pulmonary artery balloon flotation catheters. The mean patient age was 63 ± 14 years (range 28 to 81). No patient had pulmonary artery systolic pressure >50 mm Hg, or known restrictive or obstructive lung disease. All patients were physically capable of sitting erect without support, and were undergoing wall motion scintigraphic studies for clinical reasons.

Protocol: PCWP was measured and recorded (Hewlett-Packard 7754A 4-channel strip recorder) during the performance of technetium-99m cardiac blood pool scintigraphy. Patients underwent nonzoomed imaging while sitting upright (24 patients), lying supine (19 patients), or in both positions (12 patients). Mean PCWP was measured at end-expiration during normal breathing. Zero calibration for determination of PCWP was at the mid-axillary line in the fourth intercostal space. After initial imaging, Albumisol® was administered at the rate of 250 ml/15 minutes if PCWP was <12 mm Hg, and repeated as necessary to increase PCWP to the clinically desired level. In 2 patients, elevated PCWP decreased during spontaneous diuresis in the early postinitial imaging time period. All patients who had changes in PCWP had concomitant imaging and PCWP determination repeated 60 to 120 minutes after initial imaging.

Imaging procedure: After intravenous injection of 30 mCi of technetium-99m in vitro labelled autologous red blood cells,[10] patients underwent imaging with a mobile scintillation camera (Ohio Nuclear 410) equipped with an all-purpose parallel-hole collimator and a mobile minicomputer (MDS Mugacart). Patients were imaged in 1 or more of 3 ways: posterior imaging while sitting erect (1 million counts, nongated); left anterior oblique (LAO) 45° gated imaging while sitting erect; LAO 45° gated imaging in the supine position. Gated images afforded 250,000 counts in each of 16 frames per cardiac cycle. Resulting images were displayed in a 64 × 64 word mode matrix.

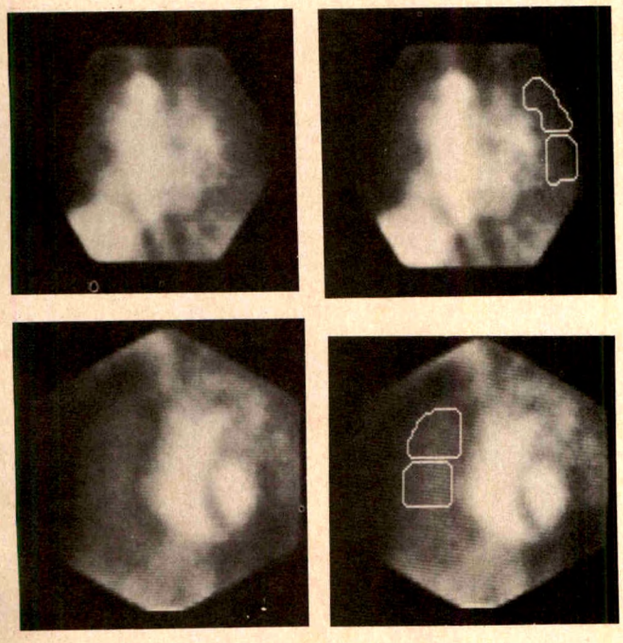

FIGURE 1. Posterior erect image (**top left**) with defined apical and basal regions of interest (**top right**). LAO 45° erect composite-gated image (**bottom left**) with apical and basal regions of interest (**bottom right**).

Image analysis: For analysis of the gated LAO views, images were added to form a composite static image, which then underwent 9-point smoothing. Analysis was done directly from the smoothed posterior view nongated images.

By manual light-pen manipulation, a variably shaped and sized region of interest (ROI) was defined over the right lung apex, and a second ROI was placed over the right lung base. The respective regions of interest were as large as possible (minimum 25 pixels), were placed so that cardiac and major vascular structures were avoided, and were placed well within the outer boundaries of the lung. The apical ROI extended as high as the level of the upper edge of the aortic arch, and the basal ROI extended to the mid-right ventricular level. The total area so delineated was divided in half, with the upper half being the apex and the lower half the base. Figure 1 displays the ROI selection for representative images of the posterior and LAO 45° positions.

After selection of appropriate regions of interest designated apex (A) and base (B), the average number of counts/pixel in each ROI was determined by computer. An apex/base count ratio was defined as the average number of counts per pixel in the apex divided by the average number of counts per pixel in the base.

Data analysis and statistical methods: The A/B radioactive count ratio was compared with the simultaneously obtained PCWP for (1) each of the 24 patients imaged in the posterior erect position; (2) each of the 14 patients imaged in the LAO erect position; and (3) each of the 19 patients imaged in the LAO supine position. A linear regression analysis by the method of least squares was performed to evaluate the continuous relationship between these 2 variables for each position. Further analysis (Friedman Anova test) was undertaken to determine the consistency of the A/B ratio in the 12 patients who had images performed in more than 1 position.

An A/B ratio that exceeded unity was defined as abnormal,[4] as was a PCWP >12 mm Hg.[6] To determine the sensitivity and specificity of an abnormal A/B ratio for an abnormal PCWP, chi-square analysis was used to compare A/B ratios stratified into those ≤1 or >1 with PCWP ≤12 or >12, within each imaging position. Sensitivity was defined as the proportion of patients with PCWP >12 mm Hg who also had an A/B ratio that exceeded unity. Specificity was defined as the proportion of patients with normal PCWP (≤12 mm Hg) who had a normal A/B ratio (≤1).

The ability of the A/B ratio to track changes in PCWP after intervention was analyzed for both directional change (Sign test) and magnitude of change (Wilcoxon test).

Results

Posterior erect position: Twenty-four patients were imaged in the posterior erect position. The A/B radioactive count ratios ranged from 0.71 to 1.30, with a mean ± standard deviation of 1.00 ± 0.20 (Table I). Concomitantly determined PCWP ranged from 5 to 26 mm Hg, with a mean value of 13 ± 6 mm Hg. When A/B ratio was plotted against PCWP (Fig. 2), a strong linear correlation was found (r = 0.864; p = 0.001), so that lower A/B ratios were seen with lower values of PCWP, and higher A/B ratios identified patients with higher wedge pressures. Stratification of A/B radioactive count ratios into normal (≤1) and abnormal (>1) values revealed that an abnormal A/B ratio was a sensitive and

LAO 45° supine	0.69	19	0.001	90	67	79

The *r* value was determined by the method of least squares. Acc = accuracy (correct prediction of normal versus abnormal PCWP); n = number of patients; Sens = sensitivity; Spec = specificity.

specific indicator of an abnormal (>12 mm Hg) wedge pressure (Table II).

Of the 24 patients studied in the posterior erect position, 9 had control wedge pressures ≤12 mm Hg, and received an average of 500 ml of Albumisol each. Wedge pressure increased an average of 5 mm Hg (range 2 to 8). In 8 of 9 cases, A/B increased along with the increase in PCWP. In 1 patient, PCWP increased from 8 to 13 mm Hg and A/B did not change. In 2 patients, PCWP decreased after spontaneous diuresis; A/B decreased in both of these patients. These changes in A/B that accompanied changes in PCWP were significant in both direction (p = 0.04, Sign test) and magnitude (p = 0.01, Wilcoxon test).

For the posterior erect position, therefore, there was a strong correlation between PCWP and A/B, and a strong correlation between changing levels of PCWP and changing A/B. In addition, an A/B ratio greater than unity was strongly predictive of a PCWP >12 mm Hg.

LAO erect position: Fourteen patients were imaged in the LAO erect position. Mean PCWP was 13 ± 6 mm Hg (range 6 to 25), and mean A/B was 1.10 ± 0.20 (range 0.85 to 1.27) (Table I). The correlation between PCWP and A/B was also found to be strong in this position: $r = 0.842$, p = 0.001 (Fig. 3). Further, only 1 patient had a PCWP that was misclassified by the A/B ratio (Table II).

Four patients received volume with repeat imaging. In these patients, PCWP increased an average of 6 mm Hg, and A/B increased an average of 0.15. In all cases PCWP and A/B increased. Probably because of insufficient numbers of patients, the changes were not significant in direction (p = 0.13, Sign test) or magnitude (p = 0.07, Wilcoxon test).

LAO supine position: Nineteen patients were imaged in the LAO supine position. Mean PCWP was 13 ± 5 mm Hg, while mean A/B ratio was 1.08 ± 0.20

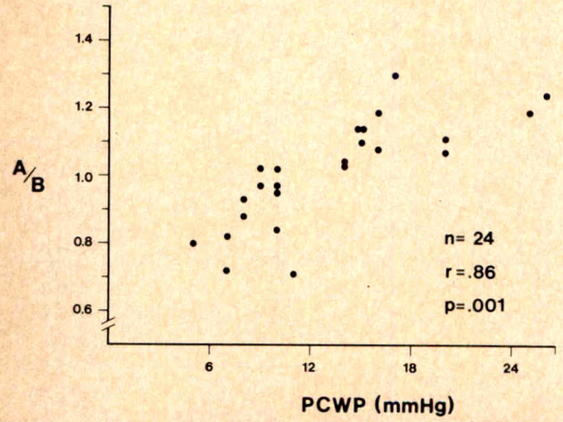

FIGURE 2. Values of A/B radioactive count ratio plotted against simultaneously measured PCWP in 24 patients imaged in the posterior erect position.

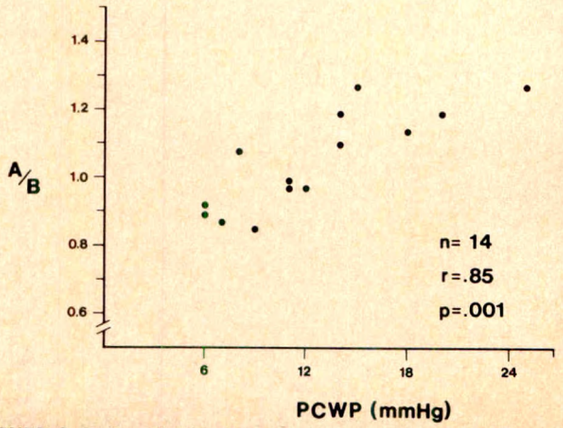

FIGURE 3. Ratios of A/B plotted against simultaneously measured PCWP in 14 patients imaged in the LAO 45° erect position.

(Table I). There was a positive correlation between PCWP and A/B, but it was not as strong as with erect imaging: $r = 0.678$, $p = 0.001$ (Fig. 4). Two of 12 patients with an A/B ratio >1.00 had a PCWP <12, and 2 of the 6 patients with A/B <1.00 had a PCWP >12 mm Hg. The sensitivity (90%), specificity (67%), and accuracy (79%) of an abnormal A/B ratio for an abnormal PCWP were considerably lower than for erect imaging (Table II). Eight patients received volume, and in all cases A/B increased along with the recorded increases in PCWP ($p = 0.01$, Sign test; $p = 0.01$, Wilcoxon test).

Correlation between the 3 positions: Twelve patients were imaged sequentially in the posterior erect, LAO 45° erect, and LAO 45° supine positions, with PCWP determined during imaging in each position. The A/B radioactive count ratios were compared for each position using the Friedman Anova test. Values obtained in the posterior erect position were found to be significantly less than those in the LAO 45° erect or supine positions ($p < 0.01$). Paired analysis with the Wilcoxon test revealed a significantly lower ($p = 0.03$) A/B ratio for posterior versus LAO 45° erect positions, and no significant difference between supine or erect LAO 45° values. When the ratios were compared across the 3 positions for the 11 male patients (Table III), the measurements in the posterior erect position were still significantly smaller than those in the LAO 45° positions. Female patients could not be examined without male patients because only 1 was imaged in all 3 positions.

Directional changes in A/B ran parallel to changes in PCWP in the posterior and supine positions. A direct numerical correlation between changes in A/B and changes in PCWP was not obtained for these positions ($r = 0.56$, $p = 0.07$; $r = 0.57$, $p = 0.14$, respectively).

Discussion

Pulmonary blood flow is normally distributed preferentially to the lung base, particularly in the upright position.[3] A redirection of blood flow toward the lung apex has been shown to occur as left ventricular filling pressure increases.[4,11] This reflects a greater relative distensibility of apical vessels, a constriction of basal vessels, and a recruitment of apical vessels that are usually closed.[12] However, blood flow is also highly dependent upon a number of factors that influence arteriolar resistance including posture, intraalveolar pressure, and adrenergic activity.[12] The distribution of pulmonary blood volume might be expected to be less sensitive to such changes, and thus to relate more directly to pulmonary venous (left ventricular filling) pressures. Indeed, pulmonary blood volume has been demonstrated by indicator dye techniques to progressively increase as left ventricular filling pressure increases, at least until exceedingly high pressures are reached.[13] The results of our study show that there is relatively more of total pulmonary blood volume in the lung base at low ventricular filling pressures, but that the apex-to-base distribution of PBV changes when PCWP rises.

TABLE III Comparison of A/B Ratio Obtained in 11 Male Patients Imaged Sequentially in 3 Positions

Position	A/B Ratio (Mean ± SD)	Range
Posterior erect	0.97 ± 0.16*	0.72–1.24
LAO 45° erect	1.01 ± 0.16	0.85–1.27
LAO 45° supine	1.08 ± 0.19	0.72–1.42

* $p < 0.01$, posterior erect versus LAO 45° erect or supine (Friedman Anova).
SD = standard deviation.

In this study, it was observed that when patients undergo imaging in the upright position, accurate estimates of wedge pressure can be made from the relative distribution of technetium-99m labeled red blood cells to the lung apex and base. In addition to providing a numerical estimate of PCWP, in the erect imaging positions this method clearly allows highly accurate identification of patients with abnormally elevated wedge pressures. Further, changes in A/B ratio track appropriately with directional changes in PCWP after intervention.

The correlation between A/B radioactive count ratios and PCWP was demonstrated to be less strong with supine imaging. This should not be surprising, as physiologic and previous radionuclide studies[4,12] have demonstrated a change in blood flow patterns with a change in posture. The reflexes that redirect blood distribution to the lung apex as wedge pressure increases remain intact,[12] but are blunted by the loss of similarly directed gravitational effects.

We attempted to establish which erect imaging position provided the best capability of evaluating PCWP. The posterior position obviates the problem of basal radioactive count attenuation due to increasing thickness as the anterior chest wall descends. This is the probable explanation for the lower A/B ratios at any given PCWP found in the posterior position. Because there was a strong correlation between A/B and PCWP for both erect positions, and because similar accuracies were found for detection of abnormal PCWP, it is dif-

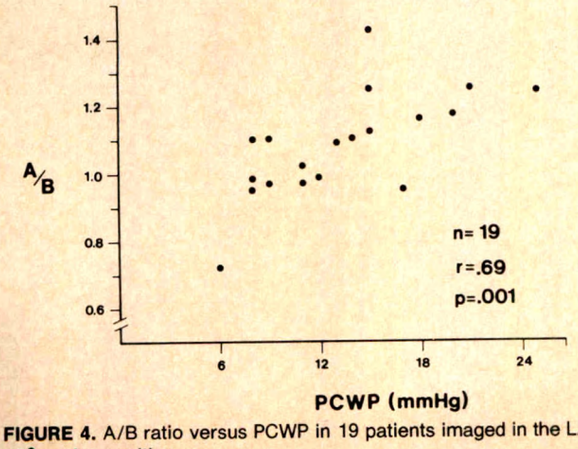

FIGURE 4. A/B ratio versus PCWP in 19 patients imaged in the LAO 45° supine position.

ficult on other than theoretical grounds to favor the posterior imaging position over the anterior.

Although this study has demonstrated the ability of an A/B ratio to estimate PCWP, the study population was too small for confident derivation of specific regression equations that might allow precise determination of PCWP. In addition, our patient group is not ideal for this purpose, because these early postoperative patients often have pleural effusions, atelectasis, and anatomic disruptions that may considerably affect the normal relationship between PCWP and A/B ratio. The finding of an imperfect relationship between changing levels of PCWP and changing A/B ratios probably also reflects this problem, as "leaky" vasculature is common early after open-heart surgery, excessive volume was frequently required to make small changes in PCWP, and an increased extravascular lung fluid would lead to intravascular radioactive count attenuation and changed A/B-PCWP relationships. Other limitations exist for the precise determination of PCWP by equilibrium blood pool scintigraphy: (1) The A/B ratio will be affected by the relative amounts of radioactivity arising from or attenuated by non-PBV sources. In thick-chested or big-breasted patients, considerable relative attenuation of counts from the lung base might be expected. (2) Although a linear correlation was observed within the range of wedge pressures studied (5 to 26 mm Hg), there will be a limit to the increased distribution of PBV to the lung apex, with further increases in PCWP leading to fluid extravasation rather than to increased PBV or to changes in the distribution of PBV. (3) The radioactive counts are accumulated over time, involving therefore potential inaccuracies due to patient movement during imaging. In addition, if the basal ROI is placed too low, the possibility exists that subdiaphragmatic counts may be sampled during expiration.

Assessment of pulmonary blood volume using radionuclide techniques has previously been reported. Nichols et al[8] used inhaled carbon-14–labeled carbon monoxide and positron blood-pool imaging to detect the development of left ventricular dysfunction in exercising patients: pulmonary blood volume increased only in those patients developing exercise-induced ischemia. Okada et al,[7,14] using technetium-99m, then showed that a ratio of counts, postexercise to preexercise, within a single ROI, allowed improved detection of patients with significant coronary artery disease[14] and reflected changes in PCWP during exercise.[7] Urbina et al[9] first demonstrated the potential usefulness of an apex-to-base ratio of PBV distribution in differentiating normal from abnormal PCWP. In their study however, they found a relatively poor correlation between A/B and PCWP, probably because imaging was supine, technetium labelling was in vivo, the selected regions of interest were small, and as much as 2 weeks separated scintigraphic imaging and invasive PCWP measurements. Our study, by employing in vitro labelling and simultaneous scintigraphic-PCWP testing, establishes the existence of a correlation between A/B ratios and PCWP, extends its clinical applicability to patients imaged upright or supine, posteriorly or from the LAO 45° position, and demonstrates that changing A/B ratios track appropriately with changes in PCWP.

Other noninvasive techniques have been used to assess left ventricular filling pressure.[4,15] The method described herein is rapid, simple, and widely available, and can easily be incorporated into the routine radionuclide assessment of ventricular performance. It is potentially important that the red blood cells be labeled in vitro with technetium-99m.[10] This technique has been shown to result in a labelling efficiency of approximately 95% at 30 minutes after injection,[16] ensuring that the site of origin of radionuclear activity is nearly completely intravascular. As such, regional variation in counts over the lung fields will reflect regional variation in intravascular blood volume.

We believe that the PCWP-A/B correlation is a significant finding, in that PCWP can be approximated from routinely performed blood pool scintigrams. Moreover, observation of impact of therapeutic intervention on A/B ratios allows conclusions to be drawn about the effect that the intervention has had on PCWP. In centers that perform supine imaging, a less precise estimation of PCWP can be made in this position, or an additional upright view can easily be incorporated.

Acknowledgment: We acknowledge the technical and research assistance provided by Carolyn Conklin, RN and Marjorie Raymond, RN, and the secretarial assistance of Helen Schamroth and Joye Nunn.

throughout the day by an ambulatory pati

Remler Ambulatory Blood Pressure Recorder...

Light, compact one-piece u
weighs only 25 ounces

The Remler patented Ambulatory Blood Pressure Reco has been in use for more than ten years by leading physic and research institutions throughout the world. It is a pro easy-to-use system and the only available blood pressure de that completely prints out calibrated blood pressure meas ments showing all Korotkoff sounds.

This Model M-2000 records blood pressures during the w er's working or leisure day. Wearing this unobtrusive, light-we device on a belt, your patient can easily record blood pres data onto the micro-cassette as many as sixty times daily. method *totally eliminates bias,* and the pressor effect of ar server's presence.

A further advantage of the Remler system is the substa savings in cost over manual methods for obtaining a mul series of blood pressure measurements.

***All Remler Blood Pressure Equipment displays calibrations which are directly traceable to the NATIONAL BUREAU OF STANDARDS.**

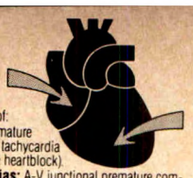
Please turn page for brief summar

QUINAGLUTE®
(quinidine gluconate)
DURA-TABS®



INDICATIONS AND USAGE:
Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:
1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).
2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).
CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.
2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.
3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.
4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.
5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.
7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.
8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.

Drug Interactions: *Drug*	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.
Less frequently encountered adverse reactions:
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.

The long-awaited text recommended by the American College of Physicians

CARDIAC THERAPY

edited by **Michael R. Rosen, M.D.,** and **Brian F. Hoffman, M.D.,**
Columbia University

Selected as part of the core library in cardiology by the American College of Physicians, this groundbreaking resource presents the most authoritative study available on the vital link between the understanding of cardiovascular pathophysiology and the delivery of effective therapy. The book focuses on three important areas: cardiac arrhythmias, cardiac failure, and myocardial ischemia. In each area, expert authors provide detailed information on the mechanisms responsible for the various disease entities, the pharmacology of therapeutic agents, and the practical and theoretical problems of clinical care. This is a must text for cardiologists, pharmacologists, internists, and all health professionals seeking state-of-the-art information in this complex field.

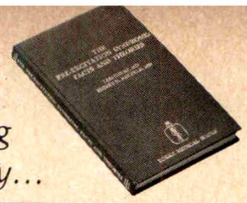
Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...



THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC
Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC
Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

Your Right to Know... The Facts in Black and White

FACT: Calan® (verapamil HCl) is the calcium antagonist consistently demonstrating antianginal benefits equal to, or greater than, propranolol, at clinically used doses in angina of effort.[1,2,3,4,5,6]

- Calan is also effective in variant angina[7] (where spasm may be exacerbated by propranolol[8]) as well as in unstable angina.[9]

FACT: In direct-comparative studies, the antianginal benefits of Calan were reported to be unsurpassed by nifedipine.[10,11,12]

- In stable effort angina: "The trial demonstrated a clear difference in the antianginal efficacy of [verapamil (Calan) and nifedipine]. ...Verapamil [Calan] was more effective..."[10] In another study, the efficacy differences were not statistically significant.[11] The doses used in both studies were Calan 120 mg tid and nifedipine 20 mg tid.

  In variant angina, in the one published comparative study, Calan and nifedipine showed equal efficacy. However, this study was neither blinded nor randomized.[12]

- Studies were directly comparative, and responses to each drug were measured objectively.[10,11,12]

FACT: Calan is indicated as single-agent initial therapy for all types of angina, while nifedipine is not.[13,14]

- Nifedipine is indicated in stable effort angina only in patients refractory to or intolerant of nitrates and/or beta-blockers.[14]
- Nifedipine is indicated for unstable angina only when ECG findings indicate vasospasm or the disease is refractory to nitrates and/or beta-blockers.[14]

FACT: The potential serious cardiovascular side effects of Calan are similar to those of beta-blockers.

- Calan and propranolol have basically the same cardiovascular cautions and contraindications such as in patients with ventricular dysfunction, second- or third-degree AV block, or cardiogenic shock.[13,15] Calan is also contraindicated in the presence of sick sinus syndrome or hypotension.
- Calan rarely causes extreme fatigue or mental depression.
- Impotence, memory loss, or nightmares have not been associated with Calan use. Calan may cause constipation.
- Calan can be used without special caution in patients with angina who also have asthma, chronic obstructive pulmonary disease, diabetes mellitus, or peripheral vascular disease such as Raynaud's phenomenon.

FACT: The incidence of adverse effects of Calan and nifedipine merits comparison (see chart below).

Adverse Reactions Reported	nifedipine Uncontrolled U.S. experience in 2,100 patients. The incidence of adverse reactions in controlled studies was generally the same or higher.[14]	(Calan) verapamil Clinical studies in 1,166 patients — NOTE that similar results were seen in both controlled clinical trials and uncontrolled clinical experience.[13]
Dizziness, light-headedness	About 10%	3.6%
Constipation	2% or less	6.3%
Flushing	About 10%	*
Headache	About 10%	1.8%
Weakness	About 10%	*
Fatigue	*	1.1%
Nausea	About 10%	1.6%
CHF or pulmonary edema	**	0.9%
Peripheral edema	About 10%	1.7%
AV block: third-degree	*	0.8%
Transient hypotension	About 5%	2.9%
Palpitation	About 2%	*
Bradycardia: HR<50/min	*	1.1%
Syncope	About 0.5%	<0.5%

*Not reported in the prescribing information.[13,14]

**About 2%, "not readily distinguishable from the natural history of the disease." "It remains possible, however, that some or many of these events were drug related."[14]

Calan® (verapamil HCl) **TABLETS** 80 mg and 120 mg

Effective Angina Therapy

Please see reverse side for a brief summary of the complete prescribing information.

© 1982, Searle Pharmaceuticals Inc.

The Facts of Effective Angina Therapy

FACT: Calan® (verapamil HCl) has pharmacologic effects complementary to those of nitrates.[13]

- Like propranolol, Calan decreases myocardial contractility. Calan's effect on the SA node tends to minimize heart rate response to arterial vasodilation, leaving the rate unchanged or slightly reduced.[13]
- Nifedipine tends to cause slightly increased heart rate due to a sympathetic response to arterial dilation.[14]

FACT: Calan provides truly additive effects with propranolol when such combination therapy is necessary in the treatment of chronic stable angina.[3,4]

- In two studies involving a total of 33 patients, the additive effects of Calan with propranolol on exercise tolerance could be seen.

	Study A[3]	Study B[4]
Propranolol alone	+2 min *	+1.3 min
Calan alone	+3.2 min	+3.4 min
Calan with propranolol	+5.3 min	+4.7 min

*Difference from placebo to maximally tolerated exercise

- Combined therapy should be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function. Because of the still limited experience with combination therapy, Calan should be used alone, if possible.

FACT: Safety considerations are important with Calan, beta-blockers, and nifedipine.

- In patients with normal conduction, Calan's electrophysiologic effects are rarely clinically important.[13] However, Calan's contraindications include patients with sick sinus syndrome or second- or third-degree AV block.
- The concomitant use of digitalis with Calan or nifedipine requires caution because digoxin serum levels may increase.[16,17]
- Both Calan and nifedipine, as well as propranolol and nitrates, require monitoring during upward dose titration.[13,14,15]

For Your Patients With Angina...

Calan® TABLETS 80 mg and 120 mg
(verapamil HCl)

- Calan is the calcium antagonist with consistently demonstrated antianginal benefits equal to or greater than propranolol.
- Calan is effective in variant angina where spasm may be exacerbated by propranolol.[8]
- Calan, unlike nifedipine, has a first-line indication for stable effort angina.

FACT: All the above statements are supported by published materials.

Calan® (verapamil HCl) TABLETS 80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings),* hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Occasional elevations of liver enzymes have been reported; patients receiving verapamil should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil. **Precautions:** Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefuly monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR< 50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** Calan (verapamil HCl) is supplied in 80-mg and 120-mg sugar-coated tablets.

Sustained Limitation of Myocardial Necrosis 24 Hours After Coronary Artery Occlusion: Verapamil Infusion in Dogs With Small Myocardial Infarcts

DEREK M. YELLON, PhD, DAVID J. HEARSE, DSc, MILES P. MAXWELL, BSc, DAVID E. CHAMBERS, BS, and JAMES M. DOWNEY, PhD

Studies were undertaken to ascertain whether verapamil infusion affords a sustained limitation of myocardial injury in the dog after a 24-hour period of coronary artery occlusion. Regional myocardial ischemia was induced by an embolization procedure which did not involve thoracotomy. Immediately after embolization radioactive microspheres were administered intraventricularly to define any area of myocardial underperfusion (zone at risk of infarction). Verapamil (0.005 mg/kg/min) was then administered and maintained for 24 hours during which time the dogs were allowed to recover from anesthesia. The control group received a corresponding infusion of saline solution. After 24 hours the dogs were killed and transverse myocardial sections (3 mm) were prepared. The resulting area of necrosis was visualized by tetrazolium staining, and risk zones were visualized by autoradiography. In the control heart, 62 ± 7% of the zone at risk deteriorated to necrotic tissue, whereas in the verapamil-treated group only 18 ± 4% of the tissue in the zone at risk became necrotic. *Verapamil appeared to exert a significant ($p < 0.001$) tissue-sparing effect that was sustained for at least 24 hours after the onset of ischemia.*

During the past decade, drugs have been proposed that were thought to protect the ischemic myocardium.[1,2] Unfortunately, due to methodologic limitations, none proved efficacious to the satisfaction of all.[3,4] In fact, even the concept of myocardial infarct (MI) size reduction itself remains the subject of debate.[1,3] One factor contributing to this controversy is the failure of past studies to differentiate between a delay and a sustained prevention of myocardial damage. Recent studies from this laboratory[4] indicate that at least 1 drug, flurbiprofen, produced sizable reductions in apparent MI size when evaluated 6 hours after coronary occlusion, but the protection disappeared on evaluation at 24 hours. One group of drugs proposed to protect the ischemic myocardium are the slow calcium-channel blocking agents. These drugs have been claimed to reduce tissue injury under experimental conditions,[5–9] but again, rarely has the distinction between delaying and reducing injury been made. In a recent study, De Boer et al[10] reported that verapamil reduced MI size approximately 20%. However, those hearts were examined only 8 hours after coronary artery occlusion. In this study we subjected dogs to 24 hours of coronary occlusion to determine whether verapamil can offer a long-term protective effect.

Methods

Surgical procedures: Twenty-five greyhounds of both sexes ranging from 20 to 32 kg were anesthetized with pentobarbital sodium (30 mg/kg intravenously). Each dog also received 500,000 units of penicillin intramuscularly at the time of anesthetization to prevent infection during the subsequent experimental period. The animals were intubated and the respiration was controlled with a mixture of nitrous oxide and air. After anesthesia, a catheter was placed in the femoral artery for subsequent withdrawal of a reference sample of blood during radioactive microsphere infusion. The left carotid artery was exposed through a midline cervical incision and a specially made cannula[11] (attached to a pressure transducer) was inserted into the carotid artery and advanced down to the aortic root. The cannula was then advanced into the coronary ostium by manual probing, precise placement of the cannula being confirmed by a transition in the recorded

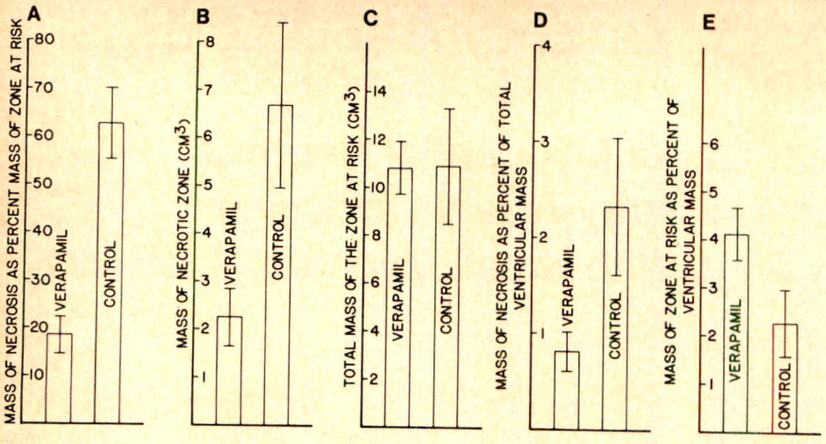

FIGURE 1. Effect of verapamil infusion or saline infusion on (**A**) the mass of necrosis (as defined by tetrazolium staining) expressed as a percentage of the zone at risk (as defined by microsphere autoradiography); (**B**) the total mass of necrotic tissue; (**C**) the total mass of the zone at risk; (**D**) the mass of necrosis expressed as a percent of the total ventricular mass; (**E**) the mass of the zone at risk expressed as a percent of the total ventricular mass. pressure from an aortic value of approximately 175 mm Hg to a peripheral coronary pressure of approximately 20 mm Hg. After placement of the cannula in the coronary ostium, a plastic bead, 2.5 mm in diameter, suspended in 20 ml of saline solution was injected through the cannula to cause coronary embolization. The cannula was then withdrawn from the coronary ostium and advanced past the aortic valve into the left ventricle (again pressure tracing confirms correct placement of the cannula in the ventricle). Cerium-141–labeled microspheres (20 million), 15 μm in diameter, were then injected through the cannula into the left ventricle. Immediately before microsphere administration, a 90-second withdrawal of arterial blood from the femoral artery was initiated. This blood sample served as a reference standard for calculation of regional myocardial blood flow.[12] After microsphere injection, the cannula was removed and the dogs were randomly divided into treatment or control groups.

Verapamil (Abbott Laboratories, United Kingdom) was prepared in normal saline solution, 0.2 mg/ml. The animals in the treatment group received a bolus injection of verapamil (0.2 mg/kg intravenously) over 2 minutes followed by a constant infusion of the drug in saline solution using an automatic pump set to deliver 0.005 mg/kg min^{-1} for up to 24 hours. The control dogs received a constant infusion of saline solution over 24 hours. Drug or saline infusion was initiated within 5 minutes of coronary embolization in all animals. Carotid exposure was then reconstructed and the animals were returned to the recovery room. To prevent thrombus formation behind the emboli, heparin (5,000 units) was added to the infusion solution in both drug and control groups. Blood samples in the treatment group were obtained periodically to determine serum drug levels. All operations were performed under strict sterile conditions to minimize the risk of infection. Heart rate, electrocardiogram, and blood pressure were recorded continuously during the operative procedure. Blood pressure changes after the bolus injection of verapamil were monitored to ensure that it did not decrease by more than 25 mm Hg.[5]

Subdivision of animals: A total of 25 dogs were used in this study. Six were excluded as a consequence of aortic rupture or aneurysm (from manual probing with the cannula) during the early operative phase. An additional 3 dogs (1 control and 2 drug-treated) were excluded as they died within 8 hours of coronary embolization, presumably as a result of ventricular fibrillation. Of the remaining 16 dogs, 8 were randomly assigned into the drug treatment series and 8 into the control group.

Tissue preparation: At the end of the 24-hour period, animals were reanesthetized and the chest was opened. The heart was removed and rinsed in water; 200 ml of isotonic saline solution at 23°C was then infused into the vasculature through the root of the aorta. The heart was then weighed and the location of the bead in the coronary bed noted. All beads were lodged either in branches of the left anterior descending coronary artery or in the circumflex artery. The heart was then frozen and sliced transversely into 3 mm thick sections using an electric meat slicer.

Histochemical visualization of zones of necrosis: To identify tissue that had become necrotic, tissue slices were immersed in a mixture of 0.4% weight/volume triphenyl tetrazolium and 0.04% weight/volume nitro blue tetrazolium in phosphate buffer (0.07 *M*, pH 7.4) at 37°C and then incubated for 20 minutes.[13,14] Viable tissue stains violet whereas necrotic tissue remains pale. The slices were then blotted dry and necrotic areas painted with a fluorescein dye to enhance interface definition.

Autoradiographic visualization of risk zones: After tetrazolium staining, the tissue slices were placed on an acrylic sheet (20 by 25 by 0.4 cm). A layer of plastic film was placed over the tissue slices, followed by a second acrylic sheet. The 2 acrylic sheets containing the stained tissue were then placed in a clamping device and frozen. Once frozen, a sheet of X-ray film (Kodak no screen NS-2T) was interposed between 1 acrylic sheet and the tissue slices, and the whole assembly was placed in a lightproof box at −20°C for a 24-hour exposure period. Just before this step, the exact position and orientation of each tissue section on the film were marked by passing a sharpened metal probe through 2 predrilled holes in the acrylic sheets, piercing both the film and the tissue. After the 24-hour exposure period, the film was removed and developed using standard developing processing methods.

Data analysis: After removal of the x-ray film for developing, the tissue slices (still frozen to 1 acrylic sheet) were taken to a cold room where a sheet of clear acetate was placed over the slices. The outline of the tissue, the 2 register holes, and the infarct were traced. The acetate sheet was then overlaid on the X-ray film using the 2 register holes to ensure precise alignment. The X-ray film revealed the blood flow pattern around the area served by the occluded artery and thus delineated the risk zone. The superimposition of the acetate tracing of the zone of necrosis on the autoradiogram thus allowed the detection of any tissue salvage or infarct extension relative to the original zone at risk. The volume of the region at risk was calculated by computerized planimetry of the risk zone for each slice and multiplying this figure by its thickness (3.0 mm). The values for the sequential slices were then added to provide the total volume for each heart.

Using the same procedure, the total volume of necrotic tissue was calculated. All results are expressed in terms of mean ± standard error of the mean (SEM).

Regional blood flow measurements: To quantitate regional myocardial blood flow, 4 samples (approximately 250 mg each) were taken from selected sites of each heart. With tetrazolium staining as a guide, 2 samples were taken from the center of the necrotic region, 1 epicardial and 1 endocardial, and 2 samples were taken from the well perfused myocardium, again epicardial and endocardial. The tissue samples were weighed and their radioactive content was measured. Blood flow was calculated using the standard equation.[15] Ischemic blood flow was expressed as a percentage of that obtained from samples taken from the well perfused myocardium and results were expressed in terms of mean ± SEM.

Results

Control series: Figure 1 (panel A) reveals that 62 ± 7% of the volume of tissue in the zone at risk, as defined by autoradiography, had become necrotic 24 hours after coronary artery occlusion. The mean volume of necrotic tissue was 6.6 ± 1.7 cm^3 (panel B), whereas the mean volume of the zone at risk (panel C) was 10.8 ± 2.4 cm^3. Thus, even in the absence of any therapeutic intervention (other than saline infusion), a proportion of the zone at risk was spontaneously "salvaged." Although not specifically investigated in this study, the greatest proportion of sparing appeared to be in the epicardial zone.

Verapamil-treated series: Figure 1 (panel A) shows that verapamil infusion dramatically reduced the volume of necrotic tissue. The volume of necrosis expressed as a percent of the zone at risk was only 18 ± 4%, which was significantly ($p < 0.001$) lower than that in the control group. Figure 1 (panel B) also shows that the absolute volume of necrotic tissue was significantly ($p < 0.05$) lower in the verapamil-treated group. A similar trend is obtained when the results are expressed as a percent of the total ventricular mass (panel D). However, there was no statistical difference between the control and verapamil-treated groups when expressed in this way. In comparing the verapamil-treated and control groups (panel C), no significant difference ($p < 0.10$) was noted between the total volume of the zones at risk.

Figure 2 shows the relation between the volume of the initial zone at risk (expressed as a percent of the left ventricular volume) and the volume of the final zone of necrosis (again expressed as a percent of left ventricular volume) after 24 hours of ischemia in both control and verapamil-treated groups. Individual points separate into 2 clearly defined populations, confirming that the drug-treated heart had a smaller volume of necrotic tissue and that in both groups the final volume of necrosis is directly proportional to the initial volume of tissue at risk.

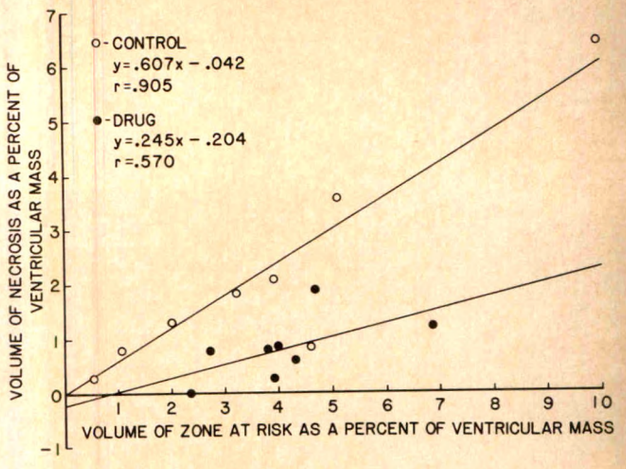

FIGURE 2. Correlation between the mass of necrotic tissue as measured at the end of 24 hours of ischemia (expressed as a percentage of ventricular mass) and the mass of the zone at risk as found at the onset of ischemia (expressed as a percentage of ventricular mass).

Hemodynamic observations: In a preliminary attempt to investigate the mechanisms underlying the verapamil-induced protection, a number of hemodynamic measurements were made before and after coronary embolization in both control and verapamil-treated dogs.

Measurements of systolic, diastolic, and mean blood pressure together with heart rate can be seen in Table I. Before embolization, there was no significant difference in any hemodynamic index between the 2 groups. Measurements taken within 5 minutes of embolization revealed that coronary occlusion had no immediate effect on any index of function. Furthermore, there was no significant difference between control dogs and those about to receive verapamil infusion. After verapamil

TABLE I Hemodynamic Assessments Before and After Coronary Artery Embolization

	Control Group				Verapamil-Treated Group			
	Blood Pressure			Heart Rate (beats/min)	Blood Pressure			Heart Rate (beats/min)
	Systolic (mm Hg)	Diastolic (mm Hg)	Mean (mm Hg)		Systolic (mm Hg)	Diastolic (mm Hg)	Mean (mm Hg)	
Preembolization	220 ±7	165 ±5	193 ±6	160 ±6	207 ±11	164 ±5	186 ±8	153 ±9
Postembolization	211 ±7	161 ±5	186 ±6	166 ±6	216 ±8	157 ±5	186 ±4	152 ±10
Drug infusion	211 ±7	161 ±5	186 ±6	166 ±6	191 ±11	132 ±11	162 ±11	140 ±11

TABLE II Residual Blood Flow During Regional Myocardial Ischemia

Group	Residual Blood Flow in Ischemic Tissue*	
	Epicardial Tissue	Endocardial Tissue
Control group before saline infusion	20 ± 6%	9 ± 3%
Drug group before verapamil infusion	14 ± 5%	8 ± 5%

* Expressed as a percentage of that in remote nonischemic tissue.

infusion, a significant and sustained reduction occurred in both systolic and diastolic pressure such that within the verapamil-treated group there was an average decrease of 24 mm Hg in mean arterial pressure. Saline infusion in the control group caused no significant hemodynamic change.

Regional blood flow measurements: To ascertain some indication of the level of collateral flow supplying the tissue after occlusion, microsphere radioactivity measurements were made. The results (Table II) indicate that in the control group of hearts, flow in the ischemic zone was reduced 80 to 90%; the mean value for collateral flow in the endocardial samples was 9.1 ± 2.8% of that measured in the nonischemic tissue remote from the ischemic zone. In the epicardial tissue, flow was somewhat higher at 20.1 ± 5.6%, reflecting the previously described[16,17] transmural gradient for residual flow. In the verapamil group, as expected, the results were the same because the microspheres were administered before the initiation of verapamil infusion.

Discussion

These results indicate that verapamil exerts a marked protective effect against ischemia in the dog heart. This protection was afforded to smaller infarcts than most other investigators employ. Part of our choice of small regions of ischemia is relative to contraints of the cannula we use to embolize the coronary vessels. A 2.5 mm diameter bead is as large as the cannula will accommodate. Another reason for our choice is to optimize the sensitivity of the method. Because the collateral support to an ischemic region is inversely related to its size,[18] drug-induced salvage is more likely to occur in a small infarct than in a large one.[19] Furthermore, the infarcting hearts are uncomplicated by cardiac decompensation and arrhythmias should be less of a problem.

We observed 38% spontaneous salvage in the control group. The reported amount of spontaneous salvage that occurs in an untreated dog varies widely in the literature. In previous studies with this same model we observed only about 10% spontaneous salvage.[4,20] Several possible explanations exist for the higher values in the present study. One control dog had only 18% necrosis of the risk zone. We have no explanation of why that occurred because the collateral flow, as revealed by the microspheres, was not abnormally high. Therefore, we included that dog in the data set. However, without that animal, the mean salvage would have been 31% which is still higher than our previous experience. There may be seasonal influences as the 2 studies were performed at different times of the year. Studies that use stereoangiography to delineate the risk zone routinely report a much higher percent of spontaneous salvage[21,22] as compared with those using dyes[23,24] or autoradiography.[4,10,24] Apparently, the stereoangiography technique systematically overestimates the risk zone and those values of spontaneous salvage are thus artifactually high.

Studies using the stereoangiography technique indicate that infarction will not occur when the risk zone involves 20% or less of the ventricle. Our results would not agree with that conclusion as the risk zones in the control group only involved 2.3% of the ventricular mass and still showed sizable infarcts. That earlier conclusion was probably a product of the systematic overestimation artifact of the risk zone by the stereoangiographic method.

A critical factor contributing to the confusion and misinterpretation of protection studies is the failure to distinguish between *reducing* and *delaying* injury. As we illustrated with the anti-inflammatory agent flurbiprofen[4] (which substantially delayed but did not ultimately reduce injury), assessments of injury as soon as 6 hours after the onset of ischemia are too soon to distinguish between delaying and preventing injury. For this reason we chose 24 hours elapsed ischemia in these studies with verapamil, and in contrast with our flurbiprofen studies we were able to show a sustained reduction of injury. Tissue that survives at the 24-hour time period is most likely to be in a stable state and unlikely to subsequently necrose. Whether survival would have continued if verapamil had been withdrawn at the 24-hour mark was not examined and must be the subject of future studies.

The possibility that verapamil may reduce the severity of myocardial ischemic injury after experimental occlusion was suggested as early as 1968 by Sodi-Pallares et al.[25] They reported that the drug was able to prevent or reverse electrocardiographic indexes of myocardial ischemia in the dog. Since then there have been relatively few studies on the effect of verapamil on infarct size in large animals. Smith et al[6–8] showed that in the dog heart with coronary artery occlusion, verapamil reduced S-T segment elevation. However, no effects on metabolism, blood flow, or enzyme levels could be detected in the ischemic tissue as a consequence of treatment.[7] Reimer et al[5] first demonstrated that verapamil could reduce necrosis during myocardial infarction. In their study the drug was given before as well as after infusion, and a very short duration of ischemia was employed (40 minutes) followed by a lengthy reperfusion (2 to 4 days). De Boer et al[10] found that verapamil reduced infarct size by a modest 20% when dogs were examined 8 hours after occlusion. To date, the only suggestion of a sustained effect of verapamil in permanent occlusion is the 1979 abstract by Ribeiro et al[26] in which they reported a 50% reduction in necrosis. Our study supports their claim.

Certain characteristics indicate that calcium antagonists are not totally homogeneous. Verapamil, D600,

and diltiazem have an almost equal calcium antagonistic effect on myocardium, pacemakers, and the vasculature, whereas nifedipine and its derivatives are prominent vasodilators and suppress contractility. However, their influence on cardiac pacemakers is small.[27] In the latest work by Zalewski et al[28] in which 5 calcium antagonists were tested, the investigators showed that *despite differences* in hemodynamic and electrophysiologic properties, all calcium antagonists tested reduced mortality and equally protected the ischemic myocardium 6 hours after coronary artery occlusion in the dog heart. Thus, the mechanism whereby verapamil limited the extent of necrosis in our study is not clear at present but might include (1) blocking ischemia-induced intracellular calcium overload and its consequent problems; (2) reducing the energy demand-supply ratio through the negative inotropic effects of the drug; or (3) specifically enhancing coronary flow to the ischemic zone. Clarification of these and other possibilities is the subject of our current investigations.

Diastolic Synchronized Retroperfusion Versus Reperfusion: Effects on Regional Left Ventricular Function and Myocardial Blood Flow During Acute Coronary Occlusion in Dogs

JEAN C. FARCOT, MD, ALAIN BERDEAUX, PharmD, JEAN F. GIUDICELLI, MD, PhD, JEAN P. VILAINE, MD, and JEAN P. BOURDARIAS, MD

The effects of 170 minutes of diastolic synchronized retroperfusion of the coronary sinus with arterial blood during 180 minutes of coronary artery occlusion on regional myocardial contractility (ultrasonic crystals) and blood flow (microspheres) were investigated in open-chest dogs. These effects were compared with those of 180 minutes of coronary occlusion and those of 170 minutes of anterograde reperfusion after 10 minutes of coronary occlusion in separate groups of dogs. Retroperfusion was able to almost restore transmural blood flow in the moderately ischemic zones and to increase it back to 47% of its preocclusion value in the severely ischemic zones with, in both zones, a favorable redistribution of flow toward the endocardium. Simultaneously, retroperfusion significantly improved segment length shortening in the moderately ischemic zones and significantly reduced the extent of paradoxical bulging in the severely ischemic zones. These partial recoveries in regional contractility and blood flow during retroperfusion were intermediate between those induced by 170 minutes of anterograde reperfusion and those of 180 minutes of coronary artery occlusion. Thus, in the presence of coronary artery occlusion, retroperfusion appears to exert a beneficial effect by improving both regional perfusion and function in the ischemic zones and may be proposed as a medical circulatory support to the jeopardized myocardium.

Coronary sinus retroperfusion with arterial blood was proposed as a possible method for treating myocardial ischemia as early as 1898.[1] Initial approaches, such as the Beck procedures,[2] were surgically oriented and consisted of anastomosing a venous graft between the aorta and the coronary veins in patients with chronic and diffuse coronary artery disease. Despite short-term clinical improvement, this technique was discarded since longer follow-up pathologic studies revealed significant damage to the coronary venous system and severe venous congestion. Subsequent retroperfusion techniques were medically oriented. Meerbaum et al[3] reported a pulsatile coronary venous retroperfusion system, synchronized with the cardiac cycle, and Farcot et al[4,5] developed a balloon-tip catheter which selectively delivers arterial blood through the great cardiac veins in diastole and allows coronary venous drainage in systole. Experimental studies by these groups have shown that diastolic synchronized retroperfusion improved myocardial metabolism and contractility and reduced the size of the ischemic zone without obvious coronary venous damage after several hours of retroperfusion.[4] More recently, Berdeaux et al[6] demonstrated with the radioactive microsphere technique that diastolic synchronized retroperfusion was capable of restoring nutritional blood flow to the ischemic myocardium up to approximately 50% of normal control flow with a preferential redistribution of flow toward the endocardium of the ischemic zone. However, the relationship between changes in regional myocardial blood flow and changes in segmental function during retroperfusion has not yet been examined.

Thus, the goal of the present investigation was to determine whether or not the increase in regional myocardial blood flow induced by diastolic synchronized retroperfusion during permanent coronary occlusion is associated with contractile function recovery

of the ischemic myocardium. The effects of retroperfusion during a 3-hour coronary occlusion period were compared with those observed in a control occlusion group and in an anterograde reperfusion group.

Methods

Twenty-two adult mongrel dogs of both sexes, weighing 22 to 34 kg, were anesthetized intravenously with sodium pentobarbital, 35 mg/kg. After endotracheal intubation, artificial respiration was controlled by a Harvard respirator pump (model 607) with room air at 12 to 15 breaths/min, and blood gases and pH were analyzed at regular intervals and maintained within the following ranges: 80 to 100 mm Hg (partial pressure of oxygen), 40 to 50 mm Hg (partial pressure of carbon dioxide), and 7.35 to 7.45 (pH). Through a thoracotomy in the fifth left intercostal space, the heart was suspended in a pericardial cradle. The left anterior descending (LAD) coronary artery was dissected free immediately after the first septal perforator for subsequent occlusion. Left ventricular (LV) pressure was measured through a catheter inserted into the left ventricle through a stab wound in the apex. Catheters were also placed in both femoral arteries and in the left atrial appendage.

As shown in Figure 1, three pairs of ultrasonic crystals were implanted into the endocardial layers, perpendicularly to the long axis of the left ventricle, 1 to 2 cm apart and varying in depth from 6 to 11 mm according to LV thickness within the free wall in potentially nonischemic, moderately ischemic, and severely ischemic zones. The labelling of these zones was confirmed after completion of the experiment. The nonischemic zone was defined as the portion of the LV wall remote from the area of distribution of the occluded vessel. The severely ischemic zone was defined as the central area of distribution of the occluded vessel and showed reductions in transmural flow and function greater than 60 and 90%, respectively. The area intermediate between the severely ischemic and nonischemic areas was considered the moderately ischemic zone.

Systemic and LV pressures were measured with Hewlett-Packard 1280C transducers, and the first derivative of LV pressure (dP/dt) was obtained by electronic differentiation. A cardiotachometer, triggered by the electrocardiogram (lead II) provided instantaneous and continuous records of heart rate.

Data were recorded on a Hewlett-Packard 8800 multichannel recorder. Retroperfusion blood flow rates were measured with a 2 mm electromagnetic T probe (Statham SP 2202 flowmeter).

Diastolic synchronized retroperfusion (DSR) was achieved by using an electrocardiographically synchronized catheter-pump system (Fig. 1), which has been previously described.[5,6] Briefly, the gas-actuated DSR cardiac synchroperfusor propels arterial blood during diastole through an 8Fr autoinflatable bladder catheter.[5] The bladder of the retroperfusion catheter located in the coronary sinus was actuated directly from the central lumen of the catheter through 2 holes. The DSR catheter was specially designed to compartmentalize the coronary sinus at the onset of diastole in order to ensure unidirectional retrograde infusion of arterial blood toward the ischemic zones.[4,5] Actuation of the retroperfusion catheter is obtained from an electropneumatic console triggered by the electrocardiogram. The tip of the DSR catheter was located in the vicinity of the Marshall vein within the higher part of the coronary sinus draining the ischemic and nonischemic zones. During diastole, retroperfusion flow through the catheter lumen delivers unidirectional low pressure (45 ± 5 mm Hg) arterial blood (60 ± 10 ml/min)[5] sampled from the femoral artery. Conversely, at the onset of systole, sudden and slight reversal of flow causes rapid and total collapse of the bladder,[4] allowing venous drainage and washout of metabolites from ischemic zones.

An improved ultrasonic transit-time dimension gauge (Schuessler, Cardiff-by-the-Sea, California) was used to measure continuously instantaneous regional myocardial segment length. The miniature ultrasonic transducers were manufactured from 3 MHz piezoelectric crystals and were approximately 2 mm in diameter with a thickness of 1 mm. The location of the crystals in the endocardial layer was confirmed at autopsy. Calibration was performed by substituting pulses of precisely known duration in 1 μs increments from a crystal-controlled pulse generator with a stability of ±0.1%.

The end-diastolic point was identified as the point following the a wave of the LV end-diastolic pressure curve just before isovolumetric contraction (rapid rise in pressure), and the end-systolic point was defined as the time at which maximum negative dP/dt occurred. From the signal produced by the transit-time dimension gauge, the end-diastolic length (EDL)

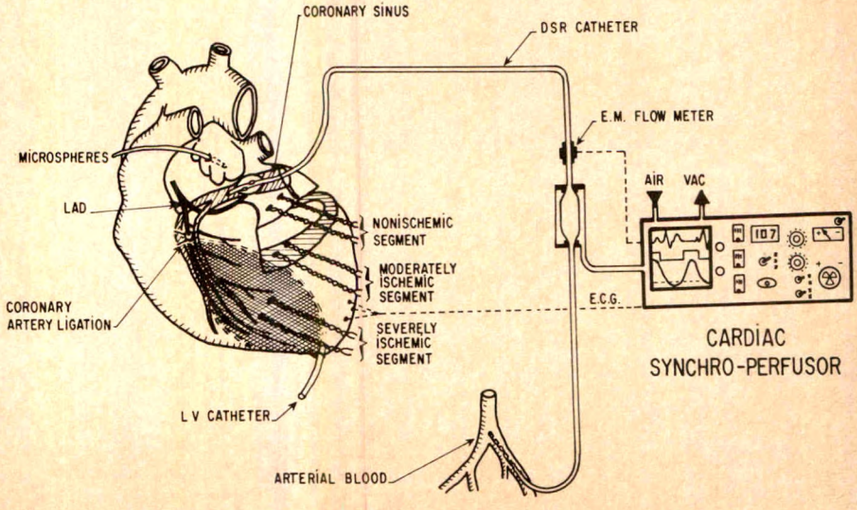

FIGURE 1. Schematic diagram of the diastolic synchronized retroperfusion experimental system. Arterial blood was shunted from a peripheral artery to the diastolic synchronized retroperfusion (DSR) catheter located in the coronary sinus. Retroperfusion was achieved by means of an air-blood unit, which was actuated by an electropneumatic cardiac synchroperfusor. The retroperfusion flow rate was monitored by an electromagnetic (EM) flowmeter probe. The **crosshatched area** indicates the zone made ischemic by left anterior descending (LAD) coronary artery occlusion. Three pairs of ultrasonic crystals were subendocardially implanted in the left ventricular wall in a circumferential plane for measurement of segment length at 3 sites: nonischemic, moderately ischemic, and severely ischemic zones. Microspheres were injected through the catheter in the left atrial appendage. ECG = electrocardiogram; LV = left ventricular; VAC = vacuum.

and end-systolic length (ESL) of the subtended myocardial segment were determined and the percent segment shortening (% ΔL) was calculated from the following formula: % ΔL = (EDL − ESL)/EDL × 100%. Each measured value was normalized to a 10 mm initial segment length by dividing the observed length by the control EDL and multiplying by 10. This method of normalizing segment dimensions was chosen because the distance between each pair of crystals was variable and arbitrarily chosen (1 to 2 cm) in relation to the actual circumference of each heart, thus making it more convenient to compare segment response among different dogs.[7,8] All data were recorded at a paper speed of 100 mm/s on the Hewlett-Packard 8800 multichannel recorder and measurements were made at end-expiration, with the respirator turned off.

Regional myocardial blood flow was measured by the radioactive microsphere technique.[9] The microspheres (New England Nuclear, Boston, Massachusetts) were suspended in 0.01% Tween® 80 solution (10% dextran) and were sonicated (50 W, Ultrasonic NSU 144 ultrasound generator) for 20 minutes and mixed by vigorous stirring with a Teflon®-covered magnet before injection. Absence of microsphere aggregation was verified by microscopic examination. Approximately 2 million microspheres (15 ± 3 μm in diameter), labelled with cerium-141, ruthenium-103, and niobium-96 suspended in 10 ml of 10% dextran, were injected through the left atrial appendage catheter for each flow determination. The choice of the radioisotope sequence was randomized. A reference sample of arterial blood was withdrawn (20 ml/min) beginning 10 seconds before microsphere injection and continuing for 80 seconds after the injection was completed. After the animal was killed, myocardial tissue samples were obtained from the sites where function had been measured. These were dissected into endocardial, mid-wall, and epicardial layers. All samples were weighed (approximately 1 to 1.5 g) and counted with appropriately selected energy windows in a gamma well counter (Compugamma, LKB Wallac, Turku, Finland). The raw counts were then corrected for background and crossover and compared with the reference blood sample to obtain flow expressed in ml/min/g of tissue. Finally, the endocardial/epicardial flow ratio was calculated.

Study protocol: The experimental protocol was conducted in 3 randomized groups of animals. In group I (n = 6), which served as the control group, LAD coronary artery ligation was maintained during 180 minutes without any further intervention. In retroperfused animals (group II [n = 7]), LAD coronary artery ligation was performed as in the control group, but synchronized retroperfusion was initiated 10 minutes after coronary occlusion and allowed to continue for 170 minutes. In reperfused animals (group III [n = 9]), the LAD coronary artery was occluded for 10 minutes and anterograde reperfusion was restored by release of the arterial ligation. In each experimental group, control measurements of LV pressure, LV dP/dt, mean aortic pressure, heart rate, and myocardial segment length shortening were obtained just before the first injection of labelled microspheres. After LAD coronary artery occlusion, hemodynamic parameters and myocardial segment length shortening were recorded at regular intervals and a second injection of microspheres was made 10 minutes after LAD occlusion when regional myocardial function and hemodynamic measurements were stable. In any event, in control animals, as well as in reperfused and retroperfused animals, hemodynamic parameters and myocardial segment length shortening were carefully recorded every 15 minutes until 170 minutes. At this time, the third injection of microspheres was performed before the animal was killed.

Results are expressed as means ± standard error of the mean (SEM). The significance of the changes produced by a given treatment from the occlusion baseline level was determined with use of Student's *t* test for paired data. Comparisons between control group and either treated group and between the 2 treated groups were done with use of a two-way analysis of variance.

Results

None of the retroperfusion-treated animals developed ventricular fibrillation or sustained ventricular arrhythmias, while 3 of the 9 reperfusion-treated animals developed ventricular fibrillation immediately or within a few minutes after LAD occlusion release.

Hemodynamic parameters: Table I summarizes the hemodynamic data in the 3 groups of animals. In all groups, coronary occlusion was associated with the usual transient increase in heart rate. Subsequently, heart rate decreased in the retroperfusion group ($-14 \pm 3\%$ at 120 minutes, $p < 0.01$, and $-17 \pm 4\%$ at 180 minutes, $p < 0.01$ from the preocclusion value) and was significantly lower ($p < 0.05$) than in the control and reperfusion groups at 180 minutes. Peak LV dP/dt was significantly reduced after 10 minutes of LAD occlusion in all groups and subsequently remained slightly depressed in the control group only. Mean arterial and systolic and end-diastolic LV pressures remained unaffected in the 3 groups throughout the experiment.

Regional left ventricular function: In the nonischemic zone (Fig. 2 and 3), there was no significant difference among the 3 groups in the preocclusion values of EDL, ESL, and percent segment shortening. Furthermore, during the 180 minute occlusion period, none of the regional LV function parameters in the 3 groups showed any significant change compared with its preocclusion value, and there was no difference at any time in the values of any parameter in the 3 groups.

In the moderately ischemic zone (Table II, Fig. 2 and 3), ESL and percent segment shortening in the control group were respectively increased ($+20 \pm 8\%$ of preocclusion value at 180 minutes, $p < 0.01$) and decreased ($-77 \pm 9\%$ of preocclusion value at 180 minutes, $p < 0.001$). After LAD occlusion release in the reperfusion group, all regional LV function parameters almost returned to preocclusion values within 120 minutes. In the retroperfusion group, regional LV function parameters improved steadily during the retroperfusion period, ESL and percent segment shortening values at 180 minutes being increased and decreased, respectively, by only $10 \pm 4\%$ and $-47 \pm 11\%$ compared with preocclusion values. These values, although significantly improved compared with the corresponding values in the control group, remained significantly lower than those in the reperfusion group ($p < 0.05$).

In the severely ischemic zone (Table III, Fig. 2 and 3), ESL and percent segment shortening in the control

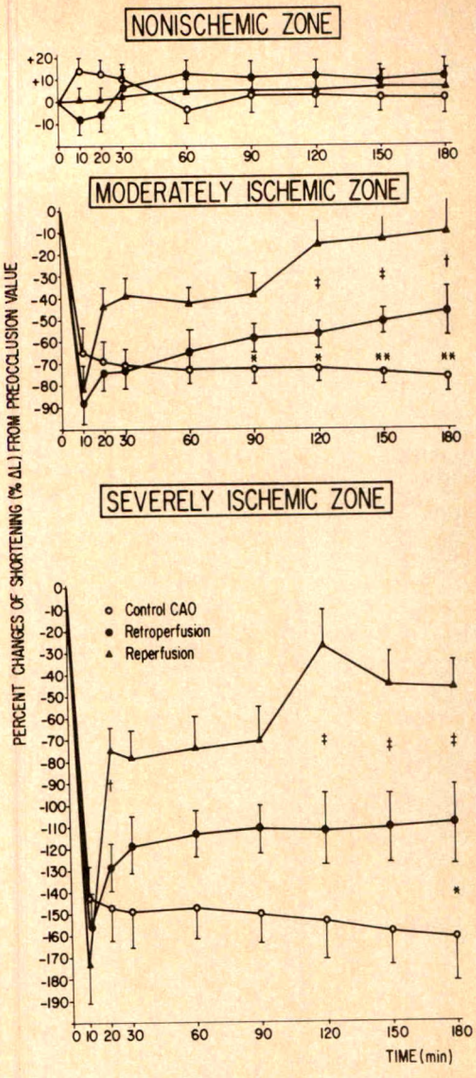

FIGURE 2. Kinetics of the percent changes (from preocclusion values) of contractile function in the nonischemic, moderately ischemic, and severely ischemic zones in the control occlusion group (**open circles**), the retroperfused group (**closed circles**), and the reperfused group (**triangles**) during the 180 minutes after coronary artery occlusion (CAO). Values for percent segment shortening have been normalized to preocclusion control values to facilitate comparison between groups. Percent changes in shortening above and below -100% refer, respectively, to active shortening and passive lengthening. * $p < 0.05$, ** $p < 0.01$, significant difference between control occlusion and retroperfused groups; † $p < 0.05$, ‡ $p < 0.01$, significant difference between retroperfused and reperfused groups.

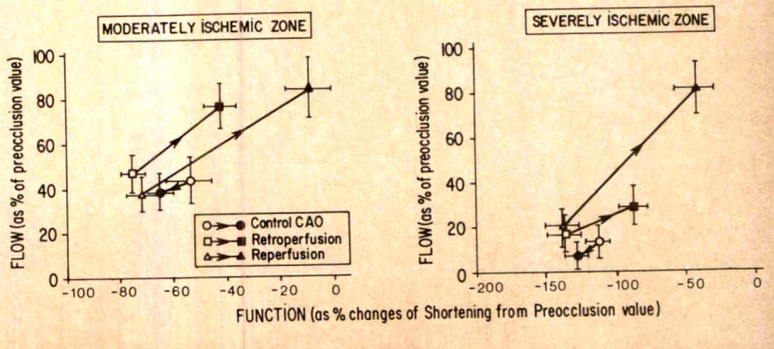

FIGURE 3. Relationship between function (percent changes in shortening from preocclusion value) and endocardial flow (percent of preocclusion flow value) changes in the moderately ischemic and severely ischemic zones. **Open symbols** correspond to flow and function values after 10 minutes of coronary artery occlusion (CAO), and **closed symbols** correspond to those observed 170 minutes later in the control occlusion group (**circles**), the retroperfused group (**squares**), and the reperfused group (**triangles**).

group were respectively increased (+36 ± 9% of preocclusion value at 180 minutes, p <0.01) and decreased (−160 ± 20% of preocclusion value at 180 minutes, p <0.001) during LAD occlusion. In the reperfusion group, regional LV function began to recover gradually as early as 10 minutes after LAD occlusion release, but at 180 minutes ESL remained increased (+9 ± 2% of preocclusion value, p <0.01) and percent segment shortening decreased (−46 ± 12% of preocclusion value, p <0.001). In the retroperfusion group, regional LV function was also improved but at 180 minutes ESL remained increased (+12 ± 5% of preocclusion value, p <0.05) and percent segment shortening decreased (−108 ± 18% of preocclusion values, p <0.001).

Although on the average, paradoxical bulging persisted at 180 minutes in the retroperfusion group, it should be pointed out that 3 of the 6 dyskinetic segments at 10 minutes of LAD occlusion reverted to hypokinesia. Furthermore, percent segment shortening at 180 minutes (−1.06 ± 1.86) was significantly increased compared with the corresponding value (−7.71 ± 2.26) at 10 minutes LAD occlusion (p <0.01). Thus, as previously observed in the moderately ischemic zone, retroperfusion afforded at 180 minutes a significant improvement (p <0.05 compared with the control group) in regional LV function, but this improvement was significantly smaller (p <0.01) than that induced by reperfusion.

Regional myocardial blood flow: In the nonischemic zone (Table IV, Fig. 3 and 4), preocclusion values of transmural, endocardial, and epicardial flows and of endocardial/epicardial ratio were similar in the 3 groups. They remained unaffected by 10 minutes of LAD occulsion as well as by subsequent treatments (reperfu-

FIGURE 4. Transmural myocardial blood flow in the nonischemic, moderately ischemic, and severely ischemic zones in the control occlusion group (**Left open bars**), in the retroperfused group (**shaded bars**) and in the reperfused group (**right open bars**) before and after 10 minutes of coronary artery occlusion (CAO) and 170 minutes later. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, significant difference from the preocclusion value; ‡ $p < 0.05$, ‡‡ $p < 0.01$, ‡‡‡ $p < 0.001$, significant difference from the 10 minute coronary artery occlusion value.

sion, retroperfusion, or permanent occlusion for 170 minutes).

In the moderately ischemic zone, transmural flow decreased to approximately 53% of its initial value after 10 minutes of LAD occlusion in the 3 groups. This reduction affected the endocardium more markedly than the epicardium, leading to a significantly reduced endocardial/epicardial ratio (approximately 28% of its initial value) in the 3 groups. Transmural, endocardial, and epicardial flows and endocardial/epicardial ratio values were not further modified at 180 minutes in the control group. Reperfusion induced an almost complete recovery in all flow parameters. Transmural flow increased significantly to a value which at 180 minutes no longer differed from the preocclusion one. This increase was more marked in the endocardium than in the epicardium, leading to a significant increase in the endocardial/epicardial ratio to a value which at 180 minutes no longer differed from the preocclusion one. Retroperfusion also significantly increased transmural flow but the value reached at 180 minutes, although not significantly different from the corresponding one in the reperfusion group, remained significantly lower than the preocclusion one. The endocardial/epicardial ratio value was also significantly increased by retroperfusion but

remained significantly lower than the preocclusion value.

In the severely ischemic zone, transmural flow values decreased to approximately 30% of their initial values after 10 minutes of LAD occlusion in the 3 groups. This reduction again affected the endocardium more markedly than the epicardium, leading to a significantly reduced endocardial/epicardial ratio (approximately 50% of its initial value) in the 3 groups. In the control group, there was a slight further reduction in flows and endocardial/epicardial ratio values at 180 minutes of LAD occlusion. Reperfusion induced an almost complete recovery in all flow parameters, and transmural, epicardial, and endocardial flows as well as endocardial/epicardial ratio values at 180 minutes did not differ from preocclusion values. Retroperfusion also significantly increased transmural flow (47 ± 7% of the initial value at 180 minutes versus 30 ± 8% of the initial value at 10 minutes, $p < 0.05$), but the value reached at 180 minutes remained significantly ($p < 0.001$) lower than the preocclusion one. However, this increase was more marked in the endocardium than in the epicardium, leading at 180 minutes to an increased endocardial/epicardial ratio compared with 10 minutes ($p < 0.05$), but the value reached at 180 minutes remained significantly lower than the preocclusion one ($p < 0.001$). Thus, retroperfusion induced a significant improvement in regional flows and endocardial/epicardial ratio values compared with the control group ($p < 0.05$), but this improvement remained significantly smaller ($p < 0.001$) than that induced by reperfusion.

Discussion

The results of the present study indicate that diastolic synchronized retroperfusion has beneficial effects on regional myocardial blood flow and function in open-chest dogs with a permanent 3 hour LAD occlusion. In order to adequately evaluate the potential regional benefits of coronary sinus retroperfusion starting 10 minutes after coronary occlusion, we compared over 170 minutes its simultaneous effects on regional myocardial blood flow and regional function to those induced either by restoration of anterograde flow after 10 minutes of coronary artery ligation alone or by maintained coronary artery ligation for 180 minutes (control group). LAD occlusion results in major ultrastructural, biochemical, and functional myocardial alterations[7,10–14] the recovery from which has been shown to be primarily dependent upon the duration of the ischemic period.[15] Therefore, in the reperfused animals, the duration of the LAD occlusion was short enough (10 minutes) to avoid irreversible myocardial necrosis and thus possibly allow a large recovery in all measured parameters. In the 2 other groups (control and retroperfused animals), coronary artery ligation lasted 180 minutes and was likely to induce comparable impairments in regional myocardial blood flow and contractile function. Furthermore, it was previously shown in dogs that these impairments rapidly reach a steady state.[12] Thus, in the ischemic zones, endocardial and epicardial flows are stable up to 2 hours after occlusion,[12] epicardial flow being only slightly increased after 6 hours.[16] Regarding contractility, ischemic myocardium begins to contract abnormally within seconds after coronary occlusion and exhibits paradoxical bulging if ischemia is severe enough.[7,8,12] However, these alterations are stable within 5 minutes and no further changes occur until 24 hours after occlusion.[12,13] This stability in regional flow and function impairments is clearly confirmed by the present study in our control group. Finally, it must be stressed that a close relationship between regional blood flow reduction and myocardial functional impairment, especially at the endocardial level, has been demonstrated in both anesthetized[17–21] and conscious dogs.[22]

The effectiveness of coronary sinus retroperfusion in partially reversing the effects of ischemia in moderately and severely ischemic zones is clearly demonstrated in this study. In moderately ischemic zones, retroperfusion was almost as effective as reperfusion in restoring transmural flow and endocardial/epicardial ratio values since the latter were not significantly different in the 2 groups at the end of the experiment. However, as shown in Figure 3, for the same increment in endocardial flow, retroperfusion-induced improvement in contractile function, which resulted in a restoration of 50% of the initial contractility, was significantly smaller than that induced by reperfusion. In the severely ischemic zone, retroperfusion increased transmural blood flow back to 47% of its preocclusion value, significantly increased the endocardial/epicardial ratio value, and significantly improved function compared with the control group; 3 of 6 segments exhibiting paradoxical bulging after 10 minutes of occlusion reverted to hypokinesia. However, these beneficial effects of retroperfusion remained significantly smaller than those induced by reperfusion, which completely restored regional myocardial blood flow and endocardial/epicardial ratio values and induced a 50% recovery in contractility, in agreement with previous data.[10,15] Thus, in both moderately and severely ischemic zones, retroperfusion significantly improved regional myocardial blood flow and function compared with that in the control group, but its beneficial effects were generally smaller than those of anterograde perfusion.

The retroperfusion-induced improvement in severely ischemic zone contractility cannot be accounted for by changes in the LV loading conditions since neither preload as reflected by nonischemic left ventricular end-diastolic length nor afterload as reflected by left ventricular systolic pressure were modified even if a slight but significant bradycardia occurred simultaneously. It also cannot be due to decrease in regional compliance since (1) left ventricular end-diastolic pressure was unchanged during retroperfusion, (2) no trend toward such a decrease in compliance was observed in the control group, and (3) the onset of the decrease in compliance has been shown not to occur at least before 7 hours after coronary occlusion. Moreover, the improvement in regional function with diastolic synchronized retroperfusion was not artifactual (that is, an "erectile effect" related to the diastolic pumping of the myocardium) since (1) the amount of blood at each diastolic stroke was small, and (2) the improvement in segmental function occurred gradually throughout the retroperfusion period and was of dif-

ferent magnitude in the moderately and severely ischemic zones. Thus, it is very likely that the beneficial effects of retroperfusion on regional contractility are related primarily to the improvement in local flows and in the endocardial/epicardial ratio, as previously suggested.[3,4,6]

It was recently shown that myocardial necrosis is directly proportional to the severity of ischemia when regional blood flow is reduced below 70 to 75% of control flow.[13] Furthermore, linear relationships between the extent of histologic necrosis and the reduction in regional blood flow measured at any time after complete coronary artery occlusion have been well documented.[17,23] Accordingly, restoring approximately 50% of preocclusion flow in the ischemic area may be expected to result in a substantial reduction of the ultimate infarct size provided coronary sinus retroperfusion is initiated early enough after coronary artery occlusion. This concept is further supported by the recent report by Smith et al[24] demonstrating that a 4 hour retroperfusion period during LAD occlusion followed by anterograde reperfusion results in a mean reduction of 84% in ultimate histologic infarct size. Finally, it must be remembered that the values of regional myocardial blood flow reported here after retroperfusion underestimate the actual enhancement of flow within the retroperfused zones since, as we showed previously,[6] 8 to 12% of the microspheres used to assess flow escape through venovenous and thebesian channels during the procedure.

The favorable redistribution of retroperfused arterial blood to the subendocardium previously reported[6] and confirmed in the present investigation suggests that coronary sinus retroperfusion might benefit the whole salvageable border zone. Preservation of subendocardium would be of major importance since it was recently shown that the contribution of subendocardial layers to the overall LV function is far more important than that of subepicardial layers during myocardial ischemia.[25]

Effects of Ortho-Iodo Sodium Benzoate on Acute Myocardial Ischemia, Hemodynamic Function, and Infarct Size After Coronary Artery Occlusion in Dogs

ROBERT E. RUDE, MD, JOHN TUMAS, BS,

Ortho-iodo sodium benzoate (OISB) decreases the affinity of blood for oxygen, thus enhancing potential tissue oxygen delivery. To test the hypothesis that a change in oxygen affinity would ameliorate regional myocardial ischemic injury resulting from occlusion of the left anterior descending (LAD) coronary artery, experiments were carried out in 55 anesthetized dogs which received an intravenous infusion of OISB. In Protocol I studies (n = 9), preocclusion intravenous infusion of OISB (500 mg/kg) reduced epicardial S-T segment elevation 15 minutes after coronary occlusion, while a similar volume of normal saline solution did not affect this index of ischemic damage. In Protocol II experiments, 34 dogs were randomized to either an OISB or saline group, after which the LAD was ligated, the chest closed, and the animal allowed to recover from anesthesia. Myocardial infarction (MI) size was assessed after the animal died or was killed 8 to 24 hours later, and was found to be 29% smaller in dogs receiving OISB. In 6 dogs, blood P_{50} (the partial oxygen pressure at which hemoglobin is 50% saturated with oxygen) was increased by OISB infusion, confirming that its administration effected a rightward shift in the oxyhemoglobin dissociation curve. Protocol III studies assessed the effects of OISB on cardiac hemodynamic function and acute myocardial ischemic damage when infusion was begun 15 minutes after LAD occlusion: average epicardial S-T segment elevation was not altered by saline solution, but decreased when OISB was infused during the last 15 minutes of myocardial ischemia. Reductions in heart rate, left ventricular dP/dt, and cardiac output were observed in 7 dogs during OISB infusion, but there were no changes in these measurements during coronary occlusion in 5 dogs receiving a constant infusion of saline solution. There were no changes in regional myocardial blood flow (microsphere technique) to either ischemic or nonischemic zones in either the saline control or OISB treatment groups.

Thus, both acute myocardial ischemic injury (assessed by epicardial electrocardiographic mapping) and ultimate MI size are reduced when OISB is infused before experimental coronary artery occlusion. OISB also reduces myocardial ischemic injury when its administration is begun 15 minutes after coronary occlusion, while effecting decreases in heart rate, left ventricular contractility, and cardiac output.

Various pharmacologic interventions are known to ameliorate acute myocardial ischemic injury and reduce infarct size in animal models of acute myocardial infarction (MI).[1,2] Some are thought to partially correct the imbalance between myocardial oxygen supply and demand in ischemic myocardium.[3] For example, beta-adrenergic blockade may decrease heart rate and contractile force, thus reducing the demand for oxygen.[4] Alternatively, coronary vasodilators may improve collateral blood flow to the ischemic zone,[5] or coronary reperfusion may reduce ischemic damage[6,7] as it restores subepicardial blood flow to nearly normal levels.[8]

Few interventions, other than those which actually increase the *volume* of blood flow to ischemic myocardium, are available to improve myocardial oxygen supply. Accordingly, we postulated that ortho-iodo sodium benzoate (OISB), a benzoic acid derivative which decreases the affinity of hemoglobin for oxygen, thus enhancing potential tissue oxygen delivery,[9–11] might ameliorate acute myocardial ischemic damage after coronary artery occlusion. data on the effects of OISB on acute myocardial ischemia and hemodynamic function in the barbiturate-anesthetized dog, and on ultimate MI size after permanent coronary artery ligation.

Methods

General methods: Fifty-five mongrel dogs of both sexes, weighing 17 to 30 kg, were anesthetized with intravenous thiamylal (20 mg/kg), intubated with a cuffed endotracheal tube, and ventilated with room air through a Harvard respirator. A thoracotomy was performed through the fifth left intercostal space, and the heart was suspended in a pericardial cradle. A lead II electrocardiogram and calibrated femoral or carotid arterial pressure were recorded on a multichannel physiologic recorder (Gould Brush Recorder model 1707). In selected dogs, the left atrium was cannulated with a polyethylene catheter for the administration of radioactive microspheres, and a micromanometer-tipped catheter (Millar Instruments model P1470) was inserted into the left ventricular chamber, either retrogradely through a carotid entry site, or directly through the apex of the left ventricle. The peak rate of rise of left ventricular pressure (LV dP/dt) was determined at end-expiration with the aid of an electronic differentiator (Biotronix Laboratory model 620).

In each dog, a portion of the left anterior descending (LAD) coronary artery was dissected free so that either temporary coronary occlusion (with a Schwartz arterial clamp) or permanent coronary ligation (with a 4-0 silk suture) could be performed. In dogs undergoing temporary coronary occlusion, either the mid-portion of the LAD or the proximal part of its major diagonal branch was chosen as the site for coronary occlusion. In animals undergoing permanent coronary ligation, the proximal portion of the LAD artery was occluded.

Epicardial electrocardiography: Epicardial electrograms were recorded during temporary coronary occlusion as follows: a soft cotton wick, soaked in physiologic saline solution, was impacted into a hollow copper cylinder 4 mm in diameter, and this apparatus was applied to predetermined epicardial sites recognized by their relation to epicardial arteries and veins. A unipolar electrogram was recorded (sensitivity of 1 mV/mm and paper speed 25 mm/s) through a standard electrocardiographic amplifier.[1] Ischemic sites for electrocardiographic recordings were chosen from areas judged to be perfused by the branch chosen for coronary occlusion. Areas adjoining the sites of dissection of the coronary artery or placement of catheters were avoided for mapping purposes because of the possibility of traumatic epicardial injury; similarly, animals requiring defibrillation were excluded because of the possibility of epicardial injury by electrical countershock. The magnitude of S-T segment elevation above the T-P segment 0.04 second after the end of the QRS complex was assessed. Sites were excluded from analysis if intraventricular conduction delay (QRS duration exceeding 0.065 second) developed, because of the invalidation of epicardial S-T segment elevation as an index of ischemia by this conduction alteration.[12] Results are expressed as $\overline{ST}$ (the average S-T segment elevation [mV] per site) at timed measurement points.

Radioactive microsphere techniques[13–15]: Regional myocardial blood flow (RMBF) and cardiac output (CO) were measured by the microsphere technique in 10 Protocol III experiments (see later). Radioactive polystyrene microspheres (9 ± 1 μm in diameter) labelled with gamma emitters (Sn^{113}, Co^{57}, Ce^{141}, Sc^{46}) were suspended with 0.2% Tween®-80 in a 50% sucrose solution, and were sonicated and agitated manually immediately before use. Approximately 2×10^6 microspheres were injected into the left atrium over 15 seconds during simultaneous withdrawal of an arterial reference sample by a Harvard syringe pump. After the animal was killed, myocardial samples from the ischemic zone and the posterolateral (nonischemic) left ventricular free wall were excised and divided into subepicardial and subendocardial halves weighing 0.5 to 1.8 g. The radioactivity of injectate standards, arterial reference samples, and myocardial tissue were measured in a gamma well counter, and after correction for background radiation and spectral overlap, RMBF was calculated as $RMBF = (C_m \times RF)/(C_r \times Wt)$, where C_m = counts in each myocardial sample, RF = arterial reference sample flow rate (15.3 ml/min), C_r = counts in the reference sample, and Wt = sample weight (g).[14] The results of calculated flow from 2 or 3 nonischemic sites were averaged and expressed as the normal epicardial and subendocardial flow for each animal. Tissue from all sites demonstrating ischemic S-T segment elevation was analyzed and a weighted average transmural ischemic zone flow was calculated on the basis of the 2 to 5 sites (2 in 1 experiment; 3 in 2 dogs; 4 in 6 dogs; 5 in 1 dog) sampled in each dog. Also, RMBF was calculated for the subepicardial and subendocardial central ischemic zone (that site demonstrating maximum S-T segment elevation). Cardiac output (systemic blood flow) was calculated from microsphere data as $C.O. = C_i \div (C_r/RF)$, where C_i = the number of counts injected.[13,15]

Infarct size determination: In dogs undergoing MI size measurements, the left ventricle was dissected from the remainder of the heart and great vessels, and cut in "breadloaf" fashion into 7 to 10 mm slices in a plane parallel to the atrioventricular groove. To delineate the area of infarction, tissue slices were incubated for 30 minutes in triphenyl tetrazolium chloride (TTC) at 37°C; this lactic dehydrogenase stain makes normal myocardial tissue stain a brick red and leaves necrotic myocardium unstained.[16–18] The changes in color produced by TTC staining are closely related to the pathologic changes of myocardial necrosis, and reliably differentiate necrotic and viable myocardium as early as 6 hours after coronary occlusion.[17] Infarcted and normal tissue in each slice was then separated by sharp dissection, and infarct size was expressed as a percentage of the left ventricle by weight. Also the distance between the left coronary ostium and the site of coronary ligation was measured by an intracoronary probe. For these determinations, the investigator performing infarct size measurements was blinded as to the treatment status of the animal.

Preparation of OISB and measurement of P_{50}: OISB was prepared for intravenous administration by the method of Litwin et al.[10] Briefly, 50 g of o-iodo-benzoic acid (Eastman Kodak, Rochester, New York) was dissolved in acetone, cooled on ice, and mixed with 8.1 g of NaOH dissolved in distilled water. The o-iodo sodium benzoate precipitate was washed with cold acetone, dessicated, and dissolved to a concentration of 225 mg/ml in sterile normal saline solution. Immediately before use, the pH of the solution was adjusted to a range of 7.40 to 7.60 by addition of HCl or NaOH.

Hemoglobin-oxygen dissociation curves on heparinized arterial blood samples were performed on a Duvelleroy dissociation curve analyzer by methods previously described.[19] P_{50}, the partial oxygen pressure (pO_2) at which hemoglobin is 50% saturated with oxygen, was noted both before and 15 minutes after administration of OISB in 6 dogs.

Experimental protocols: *Protocol I* experiments were designed to determine whether OISB affected acute myocardial ischemic injury assessed by epicardial S-T segment elevation when the agent was infused before temporary coronary occlusion. Nine animals underwent electrocardiographic mapping before and at the end of two 15-minute temporary LAD occlusions separated by 1 hour of coronary reperfusion. During the 15 minutes before the second occlusion, either

OISB (500 mg/kg, 5 dogs) or an equal volume of normal saline solution (n = 4) was infused. The average S-T segment elevation at 15 minutes after the first and second occlusion was compared in both the OISB and normal saline (control) groups.

Protocol II experiments were performed to assess the effects of pretreatment with OISB on anatomically determined infarct size after permanent coronary artery occlusion. After a transient 15-second LAD occlusion confirmed that at least two thirds of the circumference of the cardiac apex was involved by epicardial cyanosis, 34 dogs were randomized by the envelope method to treatment and control groups, and received either OISB (500 mg/kg) or an equal volume of normal saline solution over the 15 minutes preceding permanent coronary ligation. The chest was then closed, the pneumothorax was evacuated, and the dogs were allowed to awaken. Both treatment and control groups received 1 liter of normal saline solution intravenously over the first 8 postoperative hours. Infarct size was measured by the TTC technique either after the animal was killed 24 hours after coronary ligation, or after spontaneous death if it occurred at least 8 hours after coronary occlusion.[16–18]

Protocol III experiments were designed to assess (1) the effects on ischemic epicardial S-T segment elevations of OISB infusion begun after the onset of myocardial ischemia, and (2) effects of OISB on cardiac hemodynamic function (heart rate, arterial pressure, cardiac output, LV dP/dt, RMBF) during LAD occlusion. Twelve anesthetized dogs underwent 30-minute LAD occlusions and received normal saline solution (50 ml) intravenously by constant infusion during the first 15 minutes of ischemia. Thirteen minutes after LAD occlusion, the foregoing hemodynamic measurements were begun, and ischemic zone epicardial S-T segment mapping was carried out. From 15 through 30 minutes after coronary occlusion, dogs received either OISB, 500 mg/kg (treatment group, n = 7), or an equal volume of normal saline solution (control group, n = 5) by constant infusion, and hemodynamic measurements were repeated 28 to 30 minutes after LAD occlusion. Indexes of ischemic severity and hemodynamic function from the first 15-minute period were then compared with those after 30 minutes of myocardial ischemia, either at the end of OISB (treatment group) or normal saline (control group) infusion.

Statistical methods[20]: All group data are presented as the mean ± 1 standard error of the mean (SEM). Comparisons of average epicardial S-T segment elevations (Protocol I), pre- and post-OISB blood P_{50} values, cardiac output and regional myocardial blood flow data (Protocol III) were performed by Student's *t* test for paired comparisons. Intergroup comparisons of preocclusion hemodynamic variables, distance from coronary ostium to site of LAD ligation, and infarct size (Protocol II) were made using Student's *t* test for unpaired data. Comparisons of serial S-T segment elevations and hemodynamic measurements (Protocol III) were performed by an analysis of variance for repeated measures, followed by the Student-Newman-Keuls multiple range test. For all comparisons, a 2-tailed p value <0.05 was required for inference of statistical significance.

Results

Protocol I: Average S-T segment elevation at ischemic sites 15 minutes after coronary occlusion ($\overline{ST}_{15}$) in dogs receiving either normal saline solution or OISB are displayed in Figure 1. $\overline{ST}_{15}$ did not change in the 4 dogs receiving normal saline solution before the second ischemic period, being 3.4 ± 0.7 mV for both coronary occlusions. However, the 5 dogs receiving OISB before the second occlusion demonstrated a marked decrease in $\overline{ST}_{15}$ from 3.7 ± 0.3 mV to 1.1 ± 0.4 mV for the 2 occlusions, respectively ($p < 0.001$).

Protocol II: Of 59 dogs with an acceptable extent of left ventricular cyanosis after transient coronary occlusion, 2 died before randomization, and 23 (12 in control group, 11 in OISB treatment group) died within 8 hours of randomization. Protocol II measurements were performed in the 34 remaining dogs. Twenty (7 OISB and 13 control) of these 34 dogs survived for 24 hours; 14 (9 OISB, 5 control) died 8 to 24 hours after coronary occlusion (no significant difference by chi-square testing).

There was no difference in preocclusion hemodynamic variables (after equal volumes of OISB or saline were infused) between control and OISB-treated dogs. Specifically, heart rate was 149 ± 4 and 139 ± 5 beats/min in the control (n = 18) and OISB (n = 16) groups,

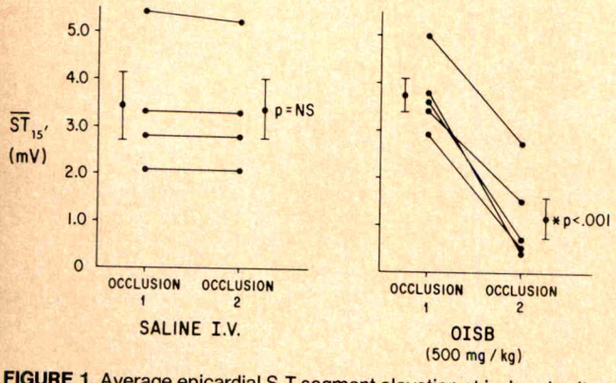

FIGURE 1. Average epicardial S-T segment elevation at ischemic sites 15 minutes after coronary occlusion ($\overline{ST}_{15'}$) is presented for serial coronary occlusions in 5 dogs receiving o-iodo sodium benzoate (OISB) before the second occlusion (**right panel**), and in 4 control dogs receiving an equal volume of normal saline before the second occlusion (**left panel**). **Bars** represent means ± standard error of the mean. I.V. = intravenous; NS = not significant.

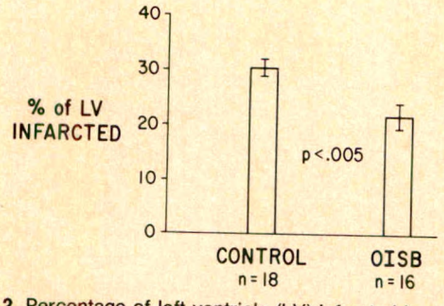

FIGURE 2. Percentage of left ventricle (LV) infarcted in control and treatment groups of dogs undergoing permanent ligation of the left anterior descending coronary artery (Protocol II). Infarct size was determined by a triphenyl tetrazolium chloride staining technique. **Bars** represent means ± standard error of the mean. Infarct size was significantly smaller ($p < 0.005$) in the treatment than in the control group (21.7 ± 2.3% and 30.5 ± 1.5% of the left ventricle for the 2 groups, respectively). n = number of animals in each group; OISB = o-iodo sodium benzoate.

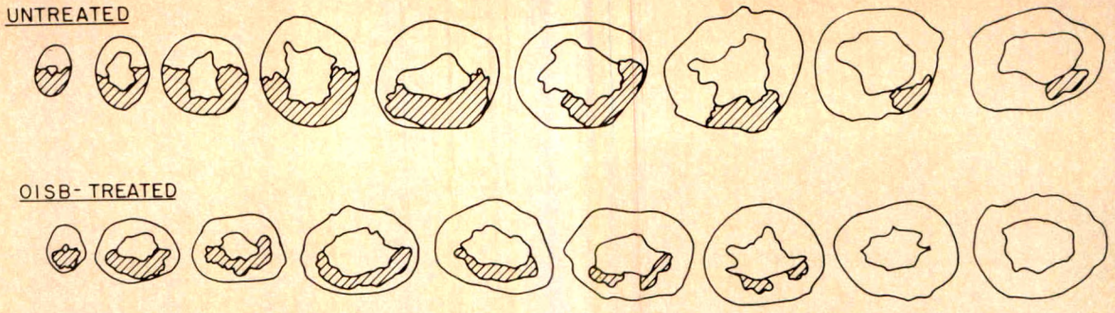

FIGURE 3. Drawings of upper (cranial) surfaces of serial transverse sections of the left ventricle below the level of left anterior descending coronary artery ligation in 2 representative dogs from Protocol II. Infarcted areas are denoted by **cross-hatching;** areas which stained normally with triphenyl tetrazolium chloride are **unshaded.** The progression of sections is from cardiac apex **(far left)** to that section including the site of coronary ligation **(far right).** The control (untreated) dog developed a large (24% of left ventricle) transmural infarction, while the dog receiving o-iodo sodium benzoate (OISB) developed a smaller (9% of left ventricle), largely nontransmural infarction.

respectively; mean arterial pressure was also similar, being 127 ± 4 and 129 ± 3 mm Hg for the 2 groups, respectively. Confirmation that the randomization process resulted in similar populations was reflected by the fact that the distance from the coronary ostium to the site of LAD ligation was similar in the 2 groups, being 2.4 ± 0.1 and 2.3 ± 0.1 cm for the control and OISB groups, respectively.

Figure 2 demonstrates the differences in infarct size between the 2 treatment groups as determined by the TTC technique. The 16 OISB-treated dogs had infarcts averaging only 21.7 ± 2.3% of the left ventricle, while control animals had an average infarct size of 30.5 ± 1.5% of the left ventricle. This 29% decrease in infarct size in the OISB group is statistically significant ($p < 0.005$). Figure 3 depicts infarcted and viable myocardium in selected dogs from the 2 treatment groups.

P_{50} measurements: In order to confirm the previously reported effects of OISB on blood oxygen affinity in the animal preparation used in these studies, arterial blood samples from 6 anesthetized dogs in Protocols I and II were obtained immediately before and 15 minutes after infusion of OISB (before coronary occlusion), and P_{50} was determined from hemoglobin-oxygen dissociation curves. P_{50} was increased by OISB infusion from 31.9 ± 0.5 to 35.7 ± 0.7 mm Hg ($p < 0.01$) (Fig. 4).

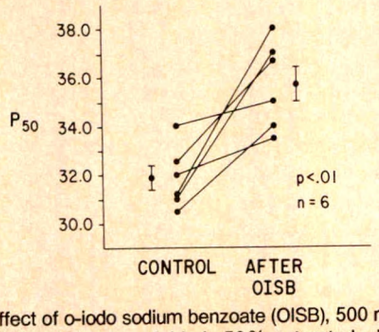

FIGURE 4. Effect of o-iodo sodium benzoate (OISB), 500 mg/kg, on P_{50} (pO_2 of blood at which hemoglobin is 50% saturated with oxygen) is shown in 6 dogs selected from Protocols I and II. P_{50} increased in each dog from control values of 31.9 ± 0.5 (standard error of the mean) to 35.7 ± 0.7 mm Hg after OISB ($p < 0.01$). Bars represent means ± 1 standard error of the mean.

Protocol III (Table I): OISB produced significant changes in hemodynamic variables and epicardial S-T segment elevations when it was infused 15 to 30 minutes after the onset of coronary occlusion (Table IA). The heart rate decreased from 164 ± 6 beats/min after the first 15 minutes of myocardial ischemia to 140 ± 7 beats/min after OISB infusion ($p < 0.001$). Left ventricular dP/dt was similar before and 15 minutes after coronary occlusion (2,224 ± 218 and 2,143 ± 204 mm Hg/s, respectively), but fell significantly (to 1,511 ± 127 mm Hg/s, $p < 0.01$ versus both previous measurement points) after 15 minutes of OISB infusion. There were no significant changes in systolic, diastolic, or mean arterial pressures throughout the study. Cardiac output decreased from 3.7 ± 0.5 liters/min after the first 15 minutes of ischemia to 2.4 ± 0.4 liters/min after OISB infusion ($p < 0.001$). There was a trend toward lower subepicardial and subendocardial myocardial blood flow to nonischemic tissue after OISB infusion, but this was not statistically significant ($0.05 < p < 0.10$). There were no differences in subepicardial or subendocardial central ischemic zone blood flows, or in transmural ischemic zone flows between the 2 measurement points. $\overline{ST}$ increased from 0 to 3.94 ± 0.58 mV ($p < 0.001$) at 15 minutes after occlusion, and decreased dramatically to 1.23 ± 0.43 mV ($p < 0.001$) after OISB infusion.

In order to confirm the stability of hemodynamic and electrocardiographic measurements in dogs undergoing coronary occlusion for the same period of time without OISB infusion, experiments were conducted in 5 control animals which received normal saline solution in volumes equivalent to the total of saline solution and OISB administered in the treatment group throughout the 30 minutes of ischemia. Results of these experiments are presented in Table IB. There were no significant changes in heart rate, arterial pressures, LV dP/dt, cardiac output, or regional myocardial blood flow to normal and ischemic zones between any of the measurement points. $\overline{ST}$ was similarly increased at 15 and 30 minutes after coronary occlusion (2.46 ± 0.38 and 2.44 ± 0.52 mV, respectively).

All dogs received 50 ml normal saline solution (NS) by constant infusion during the first 15 minutes after coronary artery occlusion. During the second 15 minutes of the same coronary occlusion, the treatment group (Part A) received o-iodo sodium benzoate (OISB), 500 mg/kg by constant infusion, while the control group (Part B) received an equal volume of NS. Data columns represent measurements before coronary occlusion (0′), at the end of NS infusion (15′), and at the end of the 30-minute occlusion (30′). Data are presented as means ± 1 standard error of the mean, and represent experiments in 7 treatment group dogs and 5 control group dogs, except for left ventricular dP/dt (LV dP/dt), where n = 5 in the OISB group and 4 in the control group, and regional myocardial blood flow (RMBF) and cardiac output (CO), when n = 6 for the treatment group and 4 for the control group.

* $p < 0.01$ versus 0′; † $p < 0.01$ versus 15′. More exact notation of p values for selected comparisons is given in the text. Cent isch = central ischemic zone; Endo = subendocardium; Epi = subepicardium; HR = heart rate; SAP, DAP, and MAP = systolic, diastolic, and mean arterial pressures, respectively; Trans isch = weighted average transmural blood flow for all ischemic tissue sampled.

Discussion

During a systematic investigation of the in vitro effects of benzoic acid derivatives on the oxyhemoglobin dissociation curve, Laver et al[9,21] found that ortho-iodo sodium benzoate was as effective as other members of this class of agents in reducing the affinity of oxygen for hemoglobin (increasing P_{50}) and that this compound was unique in this chemical series because of the absence of undesirable effects on red cell morphologic features, rheologic features, and intracellular electrolytes and pH. They also found that the increased P_{50} observed with OISB was possible in the absence of 2,3-diphosphoglycerate. Subsequent work by Gross et al[11] revealed in vitro and in vivo elevation of P_{50} in canine blood and significant elevation of P_{50} without change in arterial or coronary venous 2,3-diphosphoglycerate in an isolated supported canine heart preparation after intracoronary administration of OISB. Litwin et al[10] found significantly increased P_{50} values in dogs after a single intravenous infusion of 400 mg/kg of OISB which was sustained for 7 days in intact animals.

In the isolated heart model there is convincing evidence of a physiologically significant effect of reduction of blood oxygen affinity by OISB: during rapid atrial pacing (190 or 230 beats/min) and maintenance of constant left ventricular systolic pressure and coronary blood flow, intracoronary OISB infusion resulted in significant increases in coronary venous P_{50}, myocardial oxygen consumption, and oxygen extraction without change in coronary venous or arterial pO_2; that is, as myocardial oxygen demand was increased by tachycardia, OISB apparently enhanced oxygen release from hemoglobin and improved oxygen utilization by the myocardium while coronary venous pO_2 remained constant, thus providing an unchanged oxygen diffusion gradient across the myocardium.[11] OISB also reduced heart rate and left ventricular systolic pressure, resulting in diminished myocardial oxygen consumption and oxygen extraction as well as *increased* coronary venous pO_2 in this nonischemic isolated heart preparation.[11]

During global ischemia in the isolated canine heart (with heart rate maintained constant at 150 beats/min by atrial pacing), intracoronary OISB infusion produced significant increases in coronary venous pO_2: thus ischemic myocardium extracted more oxygen from its reduced blood supply after OISB treatment. Perhaps even more importantly, OISB treatment produced significant increases in myocardial contractile force, left ventricular systolic pressure, and LV dP/dt, suggesting OISB-related improvement in the *function* of ischemic myocardium.[11]

Because these studies suggested that OISB acts both to increase the extraction of oxygen from blood perfusing the coronary arteries and to reduce heart rate, we reasoned that this agent might have beneficial effects on the regionally ischemic heart, by effecting an increase in myocardial oxygen supply or a decrease in myocardial oxygen demands, or both. Our pilot studies (Protocol I) confirmed that this intervention, similar to others known to protect ischemic myocardium,[1–3] reduced epicardial S-T segment elevation over the ischemic zone after transient LAD coronary artery occlusions. Reduction in epicardial S-T segment elevation is thought to reflect, in a directional sense, an amelioration of myocardial ischemic injury.[1,12] To define more quantitatively the effects of OISB on the ischemic process, we performed further experiments (Protocol II) which demonstrated that administration of OISB before permanent coronary occlusion was associated with less myocardial necrosis than observed in a control group of animals with similarly placed coronary artery ligations. Randomization procedures and investigator blinding were used to eliminate sources of bias in this part of our study, and the variability in infarct size after LAD occlusion was minimized by prerandomization

exclusion of animals which did not develop cyanosis of both the anterior wall and cardiac apex during a test coronary ligation. Protocol III experiments then confirmed that OISB effected a reduction in acute ischemic injury, even when its administration was begun *after* coronary occlusion. Furthermore, OISB reduced heart rate and left ventricular contractility when it was administered after coronary occlusion (Protocol III); such changes in major determinants of myocardial oxygen consumption may have reduced myocardial oxygen demand, leading to less oxygen lack in the ischemic zone. It is not clear from our studies whether these hemodynamic alterations are physiologic concomitants of improved oxygen extraction by peripheral tissues[22] or whether they reflect a direct cardiodepressant effect of OISB. The absence of changes in either central ischemic zone or summed transmural ischemic zone regional myocardial blood flows after OISB therapy indicates that the protective effect of this intervention is not due to an increase in the volume of blood flow to ischemic tissue. These findings are compatible with the hypothesis that a decrease in blood oxygen affinity, confirmed by the increase in P_{50} after OISB infusion in a subpopulation of our study animals, allows more extraction of oxygen from available collateral blood flow, thus improving oxygenation in ischemic myocardium. Further studies will be necessary to delineate whether the negative inotropic and chronotropic effects of OISB play a major or only a supportive role in the reduction of ischemia by OISB.

Another group recently demonstrated salutary effects of reduced blood oxygen affinity on regional ischemic injury after coronary artery occlusion.[23] In these studies, infusion of a solution of glycolytic intermediates (dihydroxyacetone, phosphate, and pyruvate) produced an increase in blood P_{50} similar in magnitude to that observed in our studies with OISB; when ischemic tissue was classified according to the degree of regional blood flow reduction, dogs with reduced blood oxygen affinity had less histologic evidence of necrosis for any degree of ischemia than either control dogs or those receiving equivalent volumes of pyruvate and phosphate. The intervention tested in these studies is known to stimulate production of 2,3-disphosphoglycerate[24]; this mechanism of blood oxygen affinity reduction is different from that of OISB.[11]

We conclude that acute myocardial ischemic injury (assessed by epicardial electrocardiographic S-T segment mapping) and ultimate infarct size are reduced in dogs by infusion of o-iodo sodium benzoate before coronary artery occlusion. Furthermore, OISB infusion after the onset of coronary occlusion also reduces acute myocardial ischemic injury in anesthetized dogs. Further studies will be required to delineate more precisely the mechanism of myocardial protection by OISB and the role of it and other drugs which reduce blood oxygen affinity in efforts to ameliorate myocardial damage resulting from acute and chronic myocardial ischemia.

Acknowledgment: We express our gratitude to Professor Myron Laver for his critical review of the manuscript, to Sharon Hale for her technical assistance, and to Paulette Newingham for preparing the manuscript.

Relation of Immediate and Delayed Thallium-201 Distribution to Localization of Iodine-125 Antimyosin Antibody in Acute Experimental Myocardial Infarction

BAN AN KHAW, PhD, H. WILLIAM STRAUSS, MD,
GERALD M. POHOST, MD, JOHN T. FALLON, MD, PhD,
HUGO A. KATUS, MD, and EDGAR HABER, MD

Thallium-201 (Tl-201) distribution in acute experimental myocardial infarction (MI) (n = 18) was compared with cardiac-specific antimyosin Fab (AM-Fab) uptake, a specific marker for myocardial necrosis. When antimyosin was injected 4 hours after ligation with Tl-201 administered 23 hours 55 minutes later and measurement of myocardial distribution determined 5 minutes after intravenous administration of Tl-201, (1) Tl-201 distribution closely correlated with microsphere regional blood flow, and (2) an inverse exponential relation to iodine-125 (I-125) AM-Fab uptake was apparent. In another group of 4 animals, Tl-201 and AM-Fab were administered intravenously 4 hours after MI, and 36 hours later myocardial distribution was measured. This delayed Tl-201 distribution had a close inverse linear correlation with I-125 AM-Fab uptake. This inverse linear relation also was apparent in 28-hour-old MIs in dogs (n = 4) where collateral circulation had been established. Tl-201 was administered intravenously at 27 hours after MI, and Tl-201 distribution was determined 1 hour later. The present study demonstrated that whereas immediate Tl-201 distribution is flow-limited, delayed Tl-201 distribution is a marker of cell viability which, due to prolonged circulation time and redistribution, is not flow-limited.

Therapy to restore coronary blood flow in patients with acute myocardial infarction (MI) has been evaluated both by return of myocardial perfusion, demonstrated with thallium imaging, and the restoration of ventricular function. Since thallium-201 (Tl-201) uptake is believed to occur exclusively in nonnecrotic tissues[1,2] and early thallium uptake is linearly related to blood flow,[3–5] thallium imaging may provide the most suitable marker for acute improvement. Yasuda et al[6] demonstrated a lag in the return of function in several patients successfully treated with intracoronary streptokinase. The factors controlling the delayed distribution of thallium, however, are not as well defined. Studies by Pohost,[4] Beller,[7] and co-workers suggest that the concentration of Tl-201 in ischemic myocardium 2 to 3 hours after intravenous injection is not related to flow. It has been postulated that the late distribution of Tl-201 in myocardium is related to viable cell mass. Cardiac myosin-specific antibodies labeled with iodine-125 (I-125) localize in necrotic myocytes[8] and thus are highly specific markers for MI.[9–11] Studies were performed in experimental animals with acute coronary occlusion to compare the distribution of radiolabeled antimyosin antibody with immediate and delayed distribution of Tl-201.

Methods

Preparation of cardiac-specific antimyosin Fab (AM-Fab): Purification of canine cardiac myosin was by the method of Katz et al[12] as described previously.[9–11] Antisera were prepared in New Zealand White rabbits, and antibody specific for cardiac myosin was purified by affinity chromatography with canine cardiac myosin-Sepharose immunoadsorbent.[9] Anticardiac myosin Fab (AM-Fab) were prepared by papain digestion of purified whole antibody at 37°C for 1.5 hours at pH 7.0 by the method of Porter.[13] Fab were separated from crystallizable fragment (Fc) and undigested antibody

by chromatography on a protein-Sepharose immunoadsorbent.[14] (Protein-A binds Fc and undigested whole IgG but does not bind Fab.) AM-Fab thus obtained were concentrated by vacuum dialysis then dialyzed against 0.3 M phosphate-buffered saline solution, pH 7.0.

Antibody activity of AM-Fab was tested by degree of binding to I-125 canine cardiac myosin. AM-Fab were iodinated with I-125 by the lactoperoxidase procedure of Marchalonis.[15] I-125 (10 mCi) was used to iodinate 250 μg AM-Fab with a resultant 50 to 60% radioiodine incorporation at an enzyme to substrate ratio of 1:50. The radiolabeled AM-Fab were repurified utilizing a 10-ml myosin-Sepharose column. Active I-125-AM-Fab were desorbed from the immunoadsorbent with 5 *M* guanidine-hydrochloride and renatured by sequential dialysis with an excess of 3 *M* potassium chloride, then against phosphate-buffered saline solution. Approximately 1 to 1.5 mCi of repurified I-125-AM-Fab was obtained from each iodination for this study.

Experimental MI: Eighteen mongrel dogs were anesthetized with 30 mg/kg of pentobarbitol, intubated, and placed on a Harvard pump respirator. A thoracotomy was performed on each dog at the fourth intercostal space and the heart suspended in a pericardial cradle.[9,16] The left anterior descending coronary artery (LAD) was dissected free at approximately two-thirds the distance from apex to base and occluded with a silk ligature. This ligation usually affected approximately 30% of the left ventricular myocardium as determined by the extent of cyanosis. The thoracotomy was closed, and the animals were allowed to recover.

Experimental protocol: Three different experimental protocols (I to III) were employed to study the relation of Tl-201 distribution to viable myocardial cell mass. Each protocol was performed in 6 dogs; however, 2 dogs each from Groups I and III and 3 from Group II were lost due to ventricular fibrillation after LAD occlusion. Figure 1 is a schematic diagram of the 3 protocols. The LAD was occluded in all dogs as described previously. At 4 hours after LAD occlusion, 200 μCi of I-125-AM-Fab was administered intravenously.

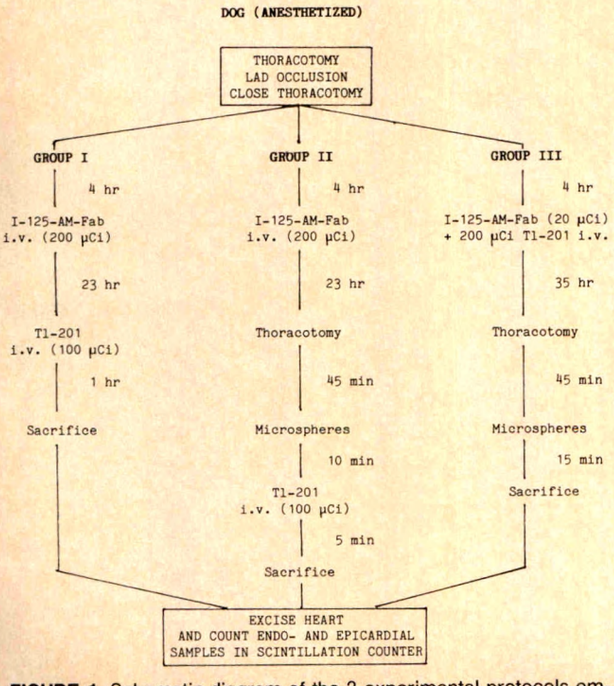

FIGURE 1. Schematic diagram of the 3 experimental protocols employed to study Tl-201 distribution with respect to viable myocardial mass as determined by cell death criteria of AM-Fab localization. i.v. = intravenously.

In Group I, each of the 4 living dogs received 100 μCi Tl-201 by intravenous injection 23 hours after administration of the I-125-AM-Fab. One hour later, the animals were killed by pentobarbitol overdose. The hearts were excised immediately and cut into 1 cm-thick ventricular slices parallel to the atrioventricular groove. Each ventricular slice was cut into 8 to 10 equal pieces and then further subdivided into epicardial and endocardial samples. All tissue samples were counted in an automatic scintillation gamma counter (Packard) for relative distribution of Tl-201 and I-125 activities. Windows were set at 80 to 200 keV for Tl-201 counting and 15 to 50 keV for I-125 activity. Corrections were made for Tl-201 activity in the iodine window. Normal epicardial and endocardial samples (4 each) obtained from the posterior left ventricular myocardium were used for comparison with the rest of the myocardial samples for distribution of various radioisotopes.

In Group II, the 3 living dogs were reanesthetized 23 hours after intravenous administration of the I-125-AM-Fab, and the thoracotomy was reopened. Forty-five minutes later, a bolus of 3×10^6 scandium-46 (Sc-46) carbonized microspheres (8 to 10 μm, 3M, St. Paul, Minnesota) was injected into the left atrium for determination of relative regional blood flow. Ten minutes after microsphere injection, 100 μCi of Tl-201 were administered by intravenous injection, and the animals were killed exactly 5 minutes later by pentobarbitol overdose. Relative distribution of I-125, Tl-201, and Sc-46 activities in the various samples of the myocardium was determined as described for Group I with an additional window of 680 to 1,000 keV for Sc-46 activity.

The 4 living dogs in Group III were given 200 μCi of I-125-AM-Fab and 200 μCi of Tl-201 intravenously simultaneously at 4 hours of LAD occlusion. Thirty-six hours later, the animals were killed. Fifteen minutes before death, a bolus of 3×10^6 Sc-46 microspheres was injected into the left atrium as previously described. The hearts were excised, and distribution of I-125, Tl-201, and Sc-46 activities in the myocardial samples was determined as described for Groups I and II.

Comparison of Tl-201 with regional blood flow: Data obtained from Groups II and III were reanalyzed for comparison of Tl-201 distribution at 5 minutes and 36 hours after intravenous injection of Tl-201 to the corresponding regional myocardial blood flow. Computer curve fitting was performed as described later.

Statistical analyses: At least 4 endocardial and 4 epicardial samples from the posterior left ventricular myocardium of each animal were employed as controls to determine mean uptake and distribution of I-125-AM-Fab and Tl-201. In studies involving comparison of relative antibody uptake to thallium distribution or relative regional blood flow, best-fit linear regression curves relating antibody uptake to Tl-201 or flow were determined by utilizing the formula $y = a + bx$, where y = log (percent blood flow) or log (percent Tl-201) and x = relative antibody uptake; or, in case of inverse relations, y = percent blood flow or percent Tl-201 and x = antibody uptake. Constants *a* and *b* were obtained by the method of Snedecor and Cochran.[17]

Results

The relation of I-125-AM-Fab localization to 1 hour of Tl-201 distribution determined at 28 hours after LAD occlusion is demonstrated in Figure 2. There is an in-

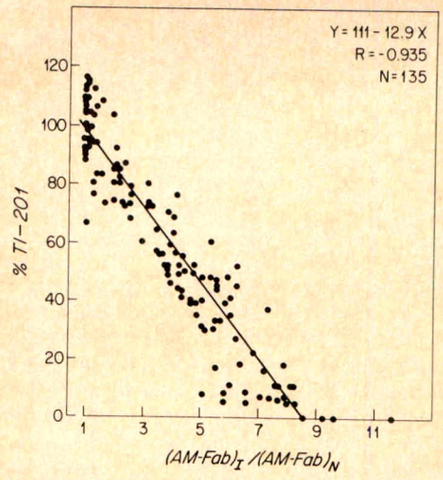

FIGURE 2. Relation between AM-Fab uptake and Tl-201 distribution in 28-hour-old experimental MI: y = 111 − 12.9x, where y = percent flow and x = (AM-Fab)I/(AM-Fab)N.

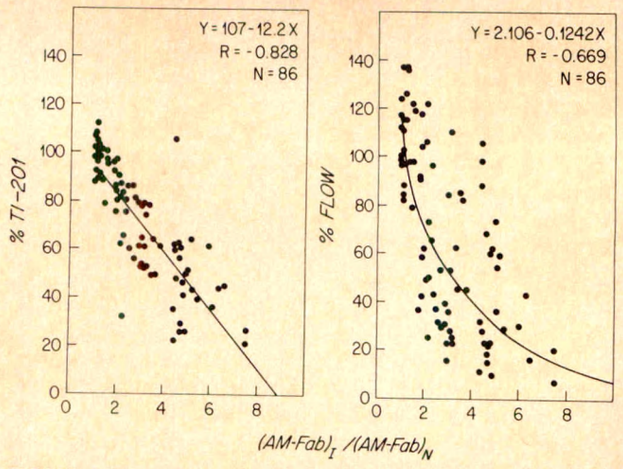

FIGURE 4. Simultaneous comparison of AM-Fab uptake and Tl-201 distribution and regional myocardial blood flow. **Left,** relation between antibody uptake and Tl-201 distribution 36 hours after antibody and Tl-201 intravenous injection. **Right,** relation between antibody uptake and regional myocardial blood flow.

verse relation between Tl-201 distribution and AM-Fab uptake. In the region of normal myocardium, determined by lack of an antibody uptake ratio above 2 (1.15 ± 0.18, mean ± standard deviation [SD]), Tl-201 distribution was 100 ± 11.2% of average normal posterior left ventricular myocardial Tl-201 distribution. Only 1 sample point showed Tl-201 distribution at 67%. The correlation coefficient was highly significant at −0.935 ($p < 0.001$). This contrasted with the Tl-201 distribution of 5 minutes (determined by injection at 27 hours 55 minutes after LAD occlusion and sacrifice of the animal 5 minutes later) compared with AM-Fab uptake at 28 hours of LAD occlusion (Fig. 3, left panel). The relations between AM-Fab uptake and blood flow and between AM-Fab uptake and Tl-201 distribution (5 minutes) were not significantly different ($r = -0.856$ and -0.85, respectively; $p > 0.5$) (Fig. 3). In regions of normal myocardium showing AM-Fab uptake of less than a ratio of 2 (1.22 ± 0.3, mean ± SD), mean regional blood flow was 88.4 ± 20.2% and mean Tl-201 distribution was 92 ± 16.9% (p = not significant [NS]).

When AM-Fab uptake at 36 hours of antibody circulation was compared with Tl-201 uptake and regional blood flow, Tl-201 distribution was inversely proportional to AM-Fab uptake ($r = -0.828$), whereas regional blood flow still showed an inverse exponential relation ($r = -0.669$, $p < 0.001$) (Fig. 4). In this delayed Tl-201 distribution study, regions of normal myocardium determined as regions with AM-Fab uptake of less than a ratio of 2 (1.34 ± 0.3) showed mean Tl-201 distribution of 95.3 ± 8.6%, whereas mean percent flow in the same samples was 101.3 ± 25.

Figure 5 demonstrates the comparison of Tl-201

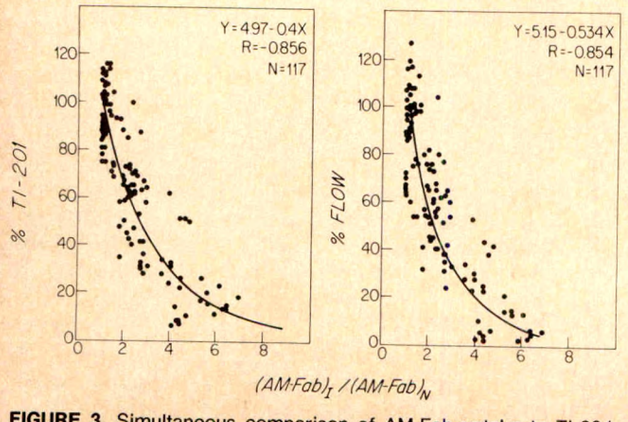

FIGURE 3. Simultaneous comparison of AM-Fab uptake to Tl-201 distribution and regional myocardial blood flow at 5 minutes of Tl-201 distribution in 28-hour-old experimental MI.

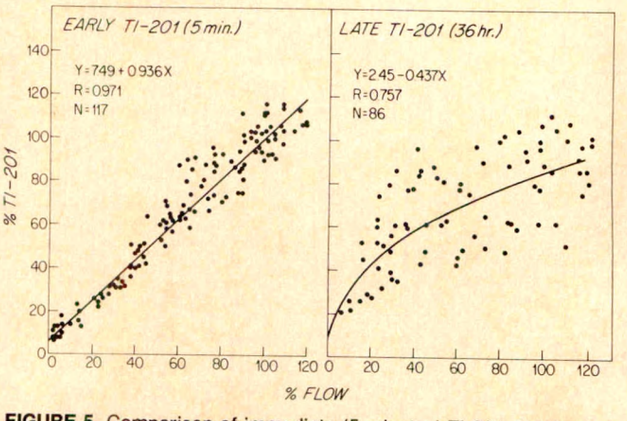

FIGURE 5. Comparison of immediate (5 minutes) Tl-201 distribution to regional myocardial blood flow at (**left**) 28 hours of coronary occlusion: y = a + bx, where y = percent Tl-201, x = percent flow, a = 7.49, b = 0.936, and $r = 0.971$, and (**right**) 36 hours of Tl-201 distribution to regional myocardial blood flows in 40-hour-old experimental myocardial infarcts: y = a + bx, where y = 1n percent Tl-201, x = percent 1n flow, a = 2.45, b = 0.437, and $r = 0.757$.

distribution to regional blood flow for 28- and 40-hour-old infarcts with Tl-201 distribution determined at 5 minutes and 36 hours of circulation. As expected, 5-minute Tl-201 distribution is reflective of regional blood flow demonstrating a direct proportionality (r = +0.971). While 36-hour distribution is diphasic, with near normal Tl-201 uptake in tissue samples in which regional flow has been reduced to 40% of normal, a more drastic reduction of Tl-201 uptake is noted in regions of hypoperfused myocardium (r = 0.757).

Discussion

We have demonstrated with primary neonatal murine myocytes in culture that antimyosin bound covalently to 1 μm polystyrene beads binds only to necrotic myocytes.[18,19] This observation was confirmed by fluorescence-activated cell sorting as well as by scanning electron microscopy. We have also previously demonstrated that antimyosin is highly specific for myocardial necrosis by macro- and microautoradiography, and by histochemical and histologic criteria.[8] Based on these studies, where antimyosin localization occurs only in necrotic myocytes, we have now used antimyosin uptake as a standard for determination of cell necrosis for comparison with Tl-201 distribution.

Tl-201 imaging, with injection either at rest or during exercise, has been used in clinical studies to identify ischemic or infarcted regions of myocardium.[1–4,7] Although many studies support the concept that the initial distribution of thallium is a linear function of blood flow,[3,4] at most clinically relevant blood flows, the factors controlling the redistribution of thallium have not been well defined. Recent studies[4,20–22] suggest that redistribution is independent of blood flow. This study suggests that the distribution of Tl-201 several hours after administration in acute MI and labeled antimyosin localization are inversely proportional. These data support the contention that delayed thallium scans represent the distribution of viable myocardium (r = −0.935 and −0.828). There appears to be little difference between 1 hour and 36 hours of thallium distribution in this relation (slopes −12.35 and −12.27, $p > 0.5$), suggesting that in an older MI where collateral circulation has already been established, serial distribution need not continue beyond 1 hour to allow evaluation of viability at least in experimental animals. However, in fresh MIs, 2 hours of Tl-201 redistribution may be required for evaluation of cell viability as observed by Pohost et al.[4]. This difference in time may be due to the difference in the amount of collateral circulation. Immediate thallium distribution (at 5 minutes), on the other hand, results in a very different slope in relation to antibody uptake (−17.9, $p < 0.01$). This relation is not significantly different from the relation between antibody uptake and flow (slope = −18.5), indicating that determination of thallium distribution 5 minutes after intravenous administration is directly proportional to regional blood flow (Fig. 5), which is in agreement with reported data.[4] DiCola et al,[23] employing a 24-hour-old canine infarct model, also showed flow dependence of thallium distribution when thallium was injected shortly before the animal was killed.

Thus, at 1 hour or 36 hours after thallium injection, the distribution of radionuclide is not limited by regional blood flow in older infarcts, but appears to reflect cell viability. We have previously demonstrated that antimyosin antibodies localize specifically in infarcted myocardium over and above the extent of nonspecific adsorption of control IgG.[9–11] This specificity has also been demonstrated by microautoradiography[8] where only necrotic myocytes showed antimyosin localization, whereas normal myocardium did not show antimyosin adsorption. These studies indicated that antimyosin localizes only in necrotic cells. By this criterion of cell necrosis, mean thallium uptake in normal myocardium was 95.3 ± 8.6%, whereas average flow in these same samples was 101.3 ± 25% (Fig. 4). A possible explanation of the observed gradient of increasing antibody uptake and decreasing thallium uptake from normal tissue to the center of an infarcted region may well be related to a varying admixture of viable and necrotic cells. Near the periphery of the ischemic zone where the cells are largely viable, thallium is taken up, with some antibody uptake in a small number of necrotic cells. As one proceeds to the center of the infarct, there are more necrotic cells that take up antibody and fewer viable cells that take up thallium. If, however, ischemic cells take up thallium at a reduced concentration, then the cells in the periphery of the ischemic zone would show reduced thallium uptake, and since these are still viable cells, the antibody uptake would remain at about a ratio of 1. If such were the case, the relation between delayed thallium and antimyosin uptake would be similar to that of percent flow and antimyosin uptake. However, the data indicate an inverse linear relation between delayed thallium uptake and antimyosin localization, indicating that the region of MI is a mixture of viable and necrotic myocytes with maximum necrotic myocytes at the center of the MI.

In immediate (5 minutes) thallium distribution, which appears to be flow-limited, there may be regions of viable cells that take up neither thallium nor antibody. Antibody is not taken up because it is excluded by intact cell membranes. Thallium is not taken up because there has been insufficient time for adequate concentration of this radionuclide to reach cells which have the potential of adequate uptake.

The data presented in our report demonstrating delayed thallium distribution as an indicator of myocardial cell viability may be of importance in view of the recent studies utilizing intracoronary streptokinase, angioplasty, or both to recanalize occluded coronary vessels.[24–26] These invasive interventions are aimed at salvaging jeopardized myocardium. Intravenous thallium distribution images obtained before recanalization provided images of the areas at risk, whereas thallium images obtained after recanalization should provide images including areas of viable myocardium in the jeopardized zones salvaged by the intervention. The differences between the pre- and postrecanalization thallium images should provide areas of salvaged myocardium. Return of cardiac function after recanalization has not been observed to be a sensitive parameter for determination of myocardial salvage.[6] Whether Tl-201 images obtained immediately after

recanalization with a second dose of intravenous thallium would provide information regarding the salvaged myocardium is not clear; however, a delayed image after recanalization should provide areas of thallium uptake in viable myocardium. Comparison of pre- and postrecanalization thallium images should thus provide scintigraphic data demonstrating the outcome of the intervention.

In conclusion, this study has demonstrated that (1) late thallium distribution reflects cell viability rather than regional blood flow; (2) immediate thallium distribution at 5 minutes of circulation is an indicator of relative blood flow, the analysis of which may significantly overestimate the area of irreversibly damaged myocardium; and (3) the comparison of immediate and delayed Tl-201 images could provide information concerning the zone of reversible ischemic compromise.

The WHO'S WHO in Echocardiography

1983 Edition

Who pioneered ultrasound right from the start?

We did. Our first ultrasound systems were built in 1973.

And we developed the first digital scan converter for grey scale, introduced the first real-time system with B-scan image quality, and pioneered multi-modality scanning.

Who combines thi ultrasound know-how with 30 years in cardiology?

Philips Medical Systems, of course. We pioneered cardiac X-Ray Systems that permit complex projections with superb visualization without moving the patient.

And Philips continues to advance the art and science of cardiac diagnostics—with superbly engineered products, such as our fully integrated biplane systems, computerized cardiac X-Ray generators and real-time Digital Vascular Imaging.

Who offers you the sharpest image in echocardiography?

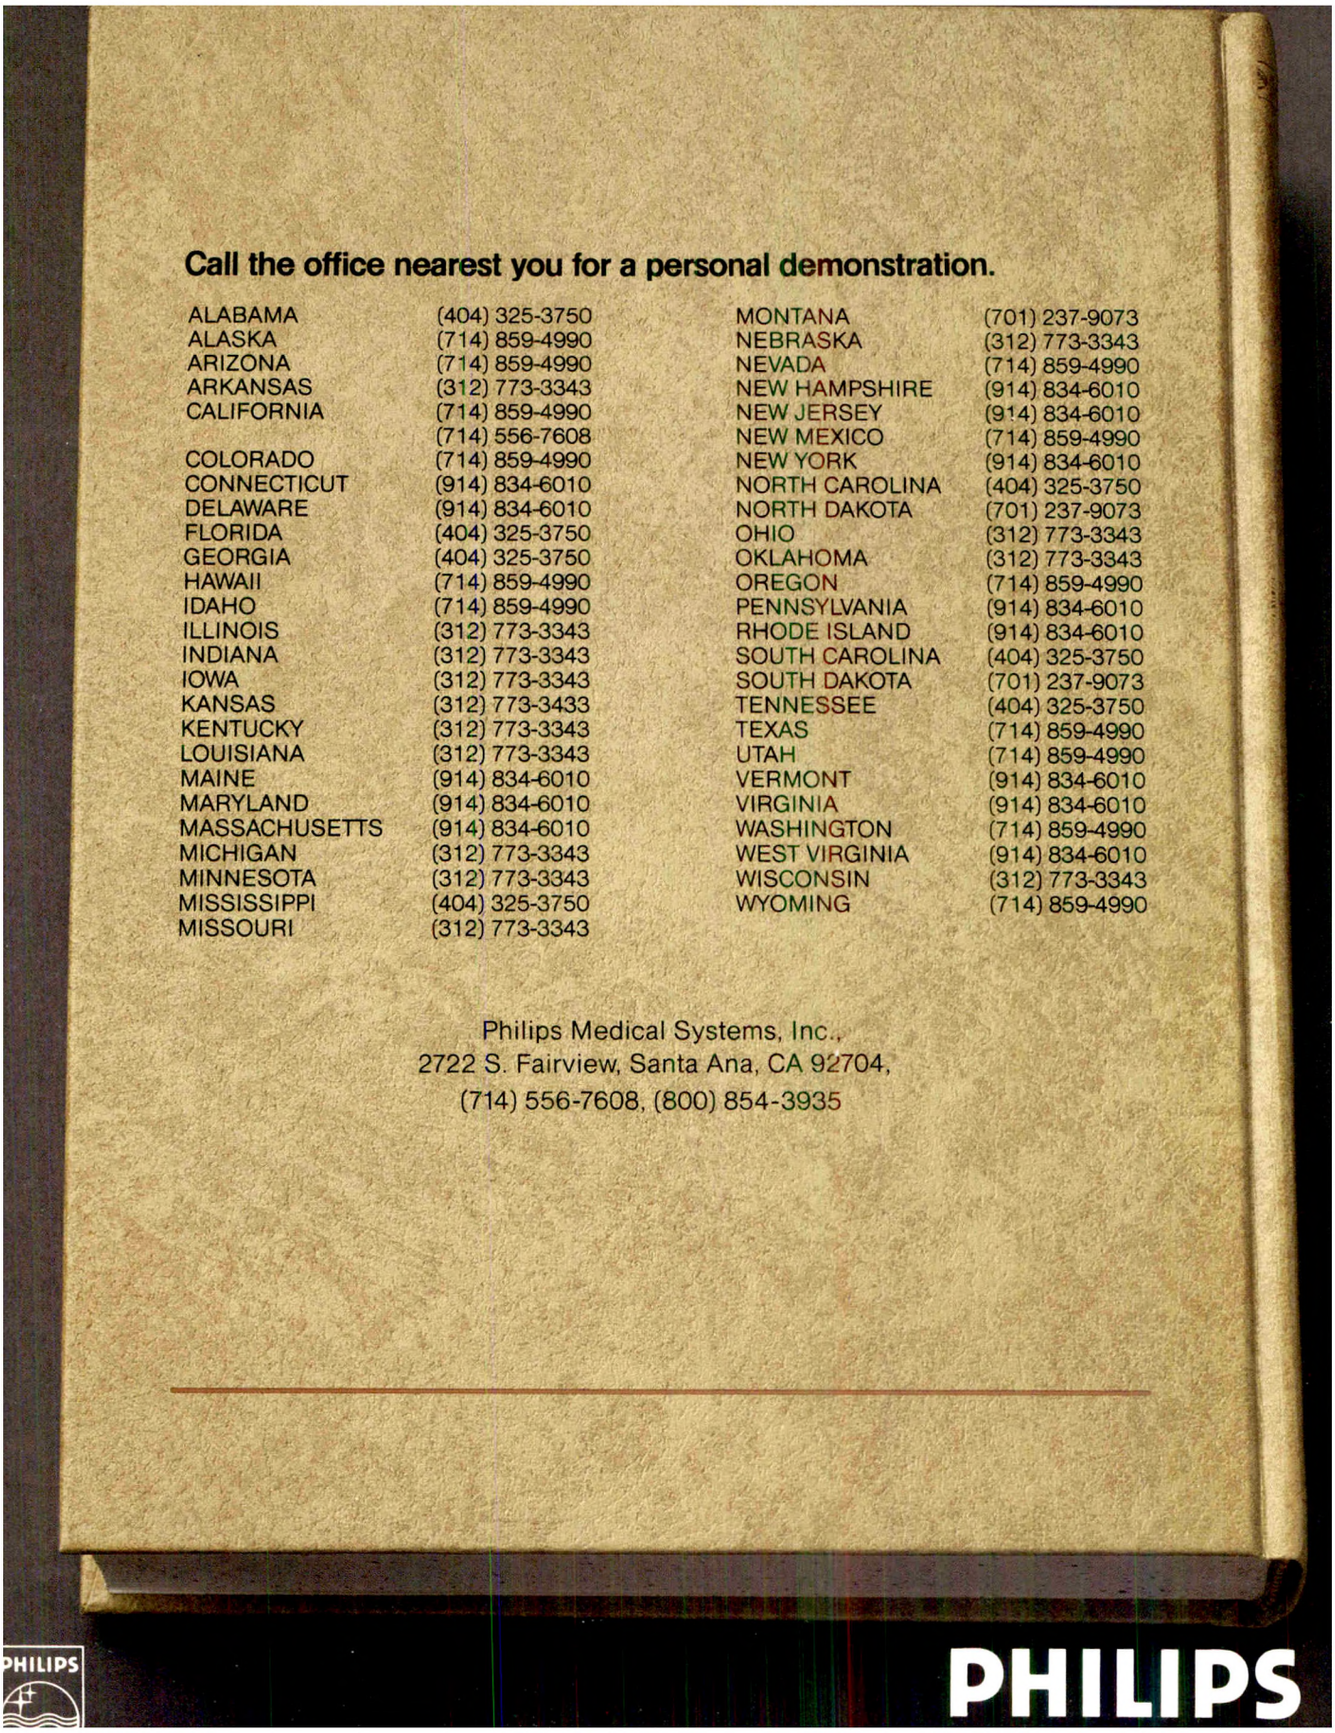
We sincerely believe that we do. But you be the judge. We personally invite you to put our SDC 4000 Echocardiography System next to anyone's.

Whichever criteria you use when choosing a system—resolution, mobility or operator convenience—the SDC 4000 is virtually unsurpassed in every category.

Whom should you talk to before you buy your next echocardiography system?

Again, the answer is Philips. Because nobody else has more experience, more know-how, more field service capability, or better image quality.

You'd be doing your Department a great service by investigating our SDC 4000 before you buy your next echocardiography system.



Call the office nearest you for a personal demonstration.

Nature of "Residual Fast Channel" Dependent Action Potentials and Slow Conduction in Guinea Pig Ventricular Muscle and Its Modification by Isoproterenol

MAKOTO ARITA, MD, TATSUTO KIYOSUE, MSc, MASAHIRO AOMINE, PhD, and SUNAO IMANISHI, MD

The nature of "residual fast channel" dependent action potentials and conduction was studied in guinea pig ventricular papillary muscle in which the resting potential was reduced to 58 ± 1 mV in high K^+ (16.7 m*M*) Tyrode's solution, with or without isoproterenol (0.1 μM). In the absence of isoproterenol, the action potential had a slur on the upstroke and the maximum rate of rise ($\dot{V}_{max}$) was composed of 2 separable peaks: the early large (32 ± 7 V/s, $\dot{V}_{max,fast}$) and the late small (10 ± 2 V/s, $\dot{V}_{max,slow}$) ones. The conduction velocity ranged from 30 to 35 cm/s. The $\dot{V}_{max,fast}$ was selectively depressed by tetrodotoxin (1 μM) and the $\dot{V}_{max,slow}$, by l-verapamil (1 μg/ml), indicating that the impulses were transmitted through incompletely inactivated ("residual") fast channels. Lidocaine (2 μg/ml) depressed $\dot{V}_{max,fast}$ with reduction of conduction velocity to about 20 cm/s just before the conduction block. Isoproterenol quadrupled the $\dot{V}_{max,slow}$ but decreased $\dot{V}_{max,fast}$. As a result, the $\dot{V}_{max,slow}$ overrode the $\dot{V}_{max,fast}$ without change in the conduction velocity. In the absence of isoproterenol, there was no rate-dependent change in the action potential duration and the effective refractory period among the rates of 0.1, 0.5, and 0.9 Hz. Isoproterenol produced rate-dependent shortening in action potential duration with rate-independent shortening of postexcitation refractoriness, thereby resulting in a significant shortening in the effective refractory period at faster rates (0.5 and 0.9 Hz). Results suggest that the "residual fast channel" could produce "slow conduction" and that the ionic channels (fast or slow) responsible for the slow conduction may alternate according to local concentrations of tissue catecholamines.

During the acute phase of myocardial ischemia, there is a rapid increase in extracellular potassium ion (K^+) concentration up to about 16 m*M* in the ischemic zone during the first 10 to 20 minutes of coronary artery occlusion in in vivo animals.[1–4] In addition, there is evidence that norepinephrine is released immediately after myocardial anoxia[5] or ischemia[6–8] from the sympathetic nerve terminals.

These conditions (hyperkalemia and catecholamines), in combination with acidosis, appear to be the most important factors responsible for arrhythmias during the early phase of ischemia because such changes should predispose to initiation of the slow response which are prerequisite for the development of reentry.[9] In fact, some ventricular arrhythmias have been successfully treated by slow channel blockers such as verapamil[10] and diltiazem.[11,12] On the other hand, there is much clinical evidence that many ventricular tachyarrhythmias related to myocardial infarction can be treated with lidocaine, which blocks the fast sodium channel without effects on the slow channel.[13] Thus uncertainties remain as to the ionic mechanism of reentry and the effectiveness of lidocaine in ventricular arrhythmias in acute myocardial infarction.[14–16] For this reason, we carried out the present experiments to clarify (1) the ionic channel or channels responsible for the impulse generation and conduction in the very early phase of acute myocardial ischemia, (2) the modification of the impulse generation and conduction by catecholamine (isoproterenol), and (3) the mode of action of antiarrhythmic drugs (lidocaine and verapamil) on such a response.

Methods

Guinea pigs weighing 250 to 300 g were killed by a blow on the neck. The heart was quickly removed and the papillary muscles (5 to 8 mm long and 0.8 to 1 mm in diameter) were excised from the right ventricle. The tendinous end of the preparation was pinned on the rubber floor of a 0.9 ml muscle chamber and the other end was fixed by a ring-shaped silver-silver chloride wire (ring electrode) wrapped 1 mm proximal to the end. Rectangular pulses of 3 ms duration were applied between the ring electrode and the small (3 by 3 mm) platinum plate was attached to the cut end of the preparation. The muscle was usually stimulated at a rate of 0.1 Hz but in some experiments at more rapid rates (0.5 to 0.9 Hz). Only cathodal pulses of constant intensity (1.5 to 2.0 times the threshold strength) were used for the stimulation because, in preliminary experiments, anodal pulses of different intensity often affected the amplitude of the maximum rate of rise ($\dot{V}_{max}$) of action potentials. Change in stimulus intensity within the range slightly changed the intervals between stimulus artifact and the action potential upstroke, but without change in the $\dot{V}_{max}$.

The muscle was perfused with normal or K^+-enriched Tyrode's solution with or without drugs. The composition of normal Tyrode's solution in mmol/liter was as follows: NaCl 137, KCl 5.4, $MgCl_2$ 1.0, $CaCl_2$ 1.8, $NaHCO_3$ 12, $NaHPO_4$ 0.4, and glucose 5.0. The high K^+ (16.7 m*M*)-Tyrode's solution was prepared by adding appropriate amounts of KCl to the normal Tyrode's solution without adjusting the osmolarity. We chose 16.7 m*M* K^+ concentration for 2 reasons: (1) extracellular K^+ concentration was reported to increase up to this level at the center of the ischemic zone in experimental myocardial infarction[2,3]; (2) preliminary experiments revealed that the split $\dot{V}_{max}$ described later (see Fig. 1) could be recognized at K^+ concentrations of 14 to 18 m*M*; and (3) K^+ concentrations over these levels (for example, 20 m*M*) resulted in inexcitable preparations in the absence of catecholamine.

In some experiments, high K^+ Tyrode's solution containing the following drugs was used: isoproterenol (Nakarai), lidocaine (Fujisawa), l-verapamil (Knoll), and tetrodotoxin (Sankyo).

The membrane potential was measured with conventional glass microelectrodes filled with 3 mol KCl (resistance, 10 to 30 MΩ). The action potentials were differentiated with an electronic differentiator having a linear amplification rate of 0 to 500 V/s. To measure the conduction velocity, 2 microelectrodes were impaled along the same line on the longitudinal axis of the preparation at a distance of 1.6 to 2.5 mm. The differentiated signals were led either to different channels (Fig. 1A) or to the same channel (Fig. 1B). The former was used to measure the amplitude of the $\dot{V}_{max}$ of each action potential, while the latter served as a feasible measure of the conduction time which was determined as the interval between 2 prominent peaks (Fig. 1B, bottom tracing). The (apparent) conduction velocity was calculated by dividing the distance between the 2 microelectrode tips by the conduction time. The signals were monitored on an oscilloscope (Nihonkoden VC-9) and recorded by a long recording camera (Nihonkoden RLG-6101).

After about 1 hour of equilibration in normal Tyrode's solution gassed with 95% oxygen-5% carbon dioxide, the muscle was initially perfused with high K^+ Tyrode's solution without the drugs followed by perfusion with the drug-containing solutions. Transitional and steady-state effects were recorded during the actions of each drug and data compared with control findings. The pH of all solutions was 7.3 and the temperature was kept at 35.0 ± 0.2°C with a constant flow rate of 3.0 ml/min.

Statistical evaluation of the results was made with Student's *t* test, and p values <0.05 were considered significant. The experiments were performed in 49 papillary muscles obtained from 40 guinea pig hearts. Nineteen preparations were used for preliminary experiments to establish the method of stimulation and to determine the external K^+ concentration which appeared pertinent to produce split $\dot{V}_{max}$. Twenty preparations were used for the experiments on depolarization phase (Fig. 1 to 7) and the rest of the preparations for the experiments on repolarization phase (Fig. 8 and 9). Only the

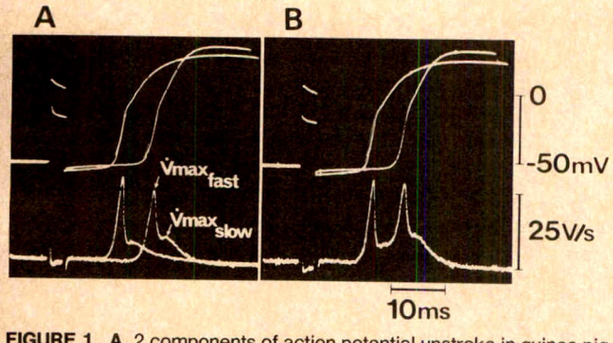

FIGURE 1. A, 2 components of action potential upstroke in guinea pig ventricular papillary muscle perfused in 16.7 m*M* K^+ Tyrode's solution and stimulated at 0.1 Hz. **Upper tracings,** action potential upstrokes obtained from 2 microelectrodes impaled 1.9 mm apart along the preparation; **lower tracings,** first derivatives of each action potential. Note initial rapid and later slow rising phase in each action potential tracing (**top**) associated with double-peaked appearance of the differentiated tracing (**bottom**), as indicated by **arrows** ($\dot{V}_{max,fast}$ and $\dot{V}_{max,slow}$). **B,** same penetration as in panel A except that here the differentiated signals were coupled to the same input of the oscilloscope to measure conduction time as a distance between the 2 peaks of the $\dot{V}_{max}$ tracing. Interelectrode distance (1.9 mm) and conduction time (6.0 ms) gave a conduction velocity of 0.32 m/s in this preparation.

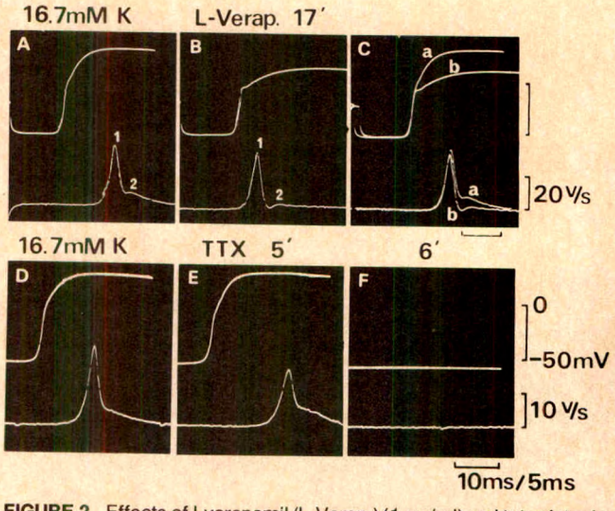

FIGURE 2. Effects of l-verapamil (L-Verap.) (1 μg/ml) and tetrodotoxin (TTX) (1 μ*M*) on the upstroke phase and $\dot{V}_{max}$ of the action potential in 16.7 m*M* K^+ Tyrode's solution. **A,** control. **B,** 17 minutes after l-verapamil. **C,** superposition of A and B. Numerals 1 and 2 denote $\dot{V}_{max,fast}$ and $\dot{V}_{max,slow}$, respectively, as indicated in Figure 1A. Note the selective decrease in $\dot{V}_{max,slow}$ with little change in $\dot{V}_{max,fast}$ by l-verapamil. **D,** control (different preparation). **E and F,** 5 and 6 minutes after application of tetrodotoxin. Note the selective decrease in $\dot{V}_{max,fast}$ (**E**) followed by complete loss of excitability (**F**).

data obtained during a continuous impalement were accepted for analysis in each experimental procedure, and the other experiments were used to support the results.

Results

Ionic mechanism of the upstroke phase in high K^+ media: An increase of K^+ in the perfusing media from normal (5.4 m*M*) to high concentration (16.7 m*M*) led to a depolarization in the resting membrane potential and depressed the action potential upstroke, as is known.[9] Figure 1A shows the high K^+-induced change in the upstroke and corresponding first derivative in action potentials recorded from 2 different points along the same preparation. The impulse was conducted from the left-hand action potential to the right.

In normal K^+ concentration, the average resting potential was -84.9 ± 4.9 mV (n = 9) and the upstroke phase consisted of a single-peaked, rapid component with a maximum upstroke velocity ($\dot{V}_{max}$) of 164.9 ± 14.0 V/s (not shown). With increase in the K^+ concentration, the upstroke changed the configuration which consisted of 2 distinct phases, as depicted by arrows in Figure 1A: an early rapid component ($\dot{V}_{max,fast}$) followed by a slow component ($\dot{V}_{max,slow}$) and resulting in a double-peaked $\dot{V}_{max}$ (split $\dot{V}_{max}$). In about 20% of the preparations tested, however, the $\dot{V}_{max,slow}$ declined rather monotonously with no discernible peak (compare with Fig. 2D, bottom tracing). In such cases, we used a point of inflection from rapid decay of the $\dot{V}_{max,fast}$ to slow decay of the $\dot{V}_{max,slow}$ to determine the amplitude of the $\dot{V}_{max,slow}$.

The average resting potential measured from 6 preparations in the high K^+ media (16.7 m*M*) was -58 ± 1 mV (range -57 to -60 mV), while the amplitude of $\dot{V}_{max,fast}$ was 32 ± 7 V/s and that of $\dot{V}_{max,slow}$, 10 ± 2 V/s.

To elucidate possible ionic channels contributing to the different upstroke phases, we used l-verapamil and tetrodotoxin, as the former blocks slow channels[17,18] and the latter blocks fast channels.[9,19]

Figure 2A to C shows the effect of l-verapamil (1 μg/ml) on the upstroke phase in the K-enriched media. The drug depressed only the late slow component with no change in the early fast component of the upstroke and resulted in a marked decrease in $\dot{V}_{max,slow}$ with little change in $\dot{V}_{max,fast}$ (Fig. 2C). The excitation was not abolished even after a prolonged application of over 30 minutes. On the other hand, Figure 2D to F represents the effect of tetrodotoxin (1 μM), which selectively depressed the early rapid upstroke, was associated with a marked decrease in $\dot{V}_{max,fast}$ (Fig. 2E), and was followed by a complete loss of excitability (Fig. 2F).

These findings suggested that in the ventricular muscle depolarized by high extracellular K^+ concentration to these potential levels, the action potential upstroke consisted of both fast and slow channels, and that the fast channel, even though it is all but inactivated by depolarization, still plays an essential role in the generation of impulse and conduction. Thus we will hereafter term the conduction "residual fast channel-dependent slow conduction."

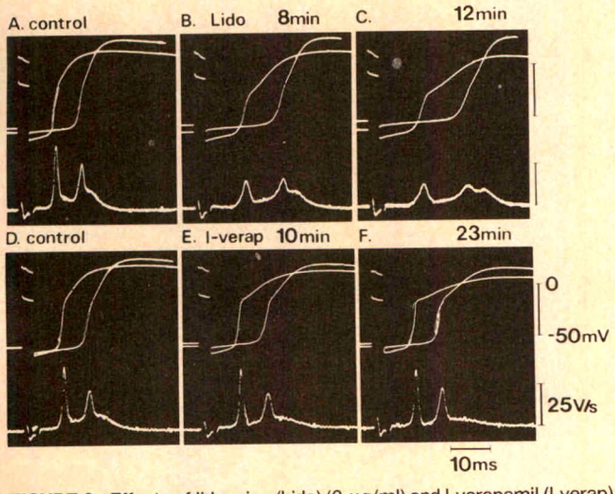

FIGURE 3. Effects of lidocaine (Lido) (2 μg/ml) and l-verapamil (l-verap) (1 μg/ml) on action potential upstroke and impulse conduction in 16.7 m*M* K^+ Tyrode's solution. **A,** control. **B and C,** 8 and 12 minutes after application of lidocaine. **D,** same preparation (30 minutes after washout of the lidocaine effects in panel C). **E and F,** 10 and 23 minutes after application of l-verapamil. Note that lidocaine decreased $\dot{V}_{max,fast}$ and lengthened conduction time (**B and C**) while l-verapamil had no effect on $\dot{V}_{max,fast}$ or conduction time but did depress $\dot{V}_{max,slow}$ (**E and F**).

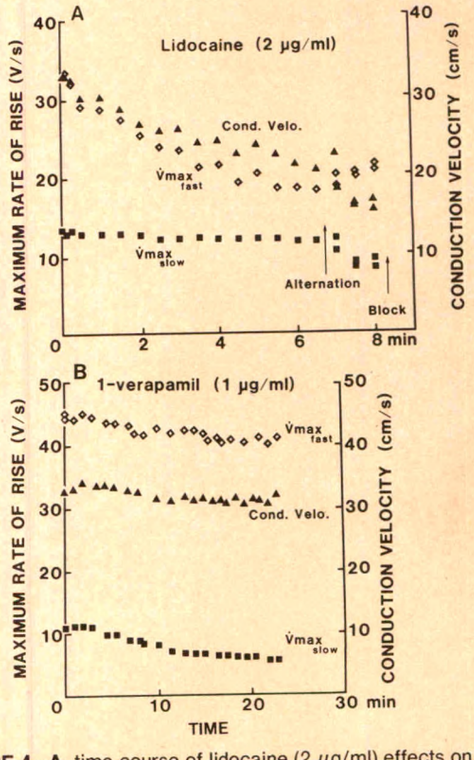

FIGURE 4. **A,** time course of lidocaine (2 μg/ml) effects on the amplitude of $\dot{V}_{max,fast}$ and $\dot{V}_{max,slow}$ (**left ordinate**) and the conduction velocity (**right ordinate**). After 7 minutes of application, the contour of the action potential began to alternate with every other beat, thus providing 2 data points on the same time scale. Eventually there was complete block of conduction after 8.5 minutes of application. **B,** time course of l-verapamil (1 μg/ml) effects on the amplitude of $\dot{V}_{max,fast}$ and $\dot{V}_{max,slow}$ (**left ordinate**) and conduction velocity (**right ordinate**). Same experiment as in Figure 3, D to F.

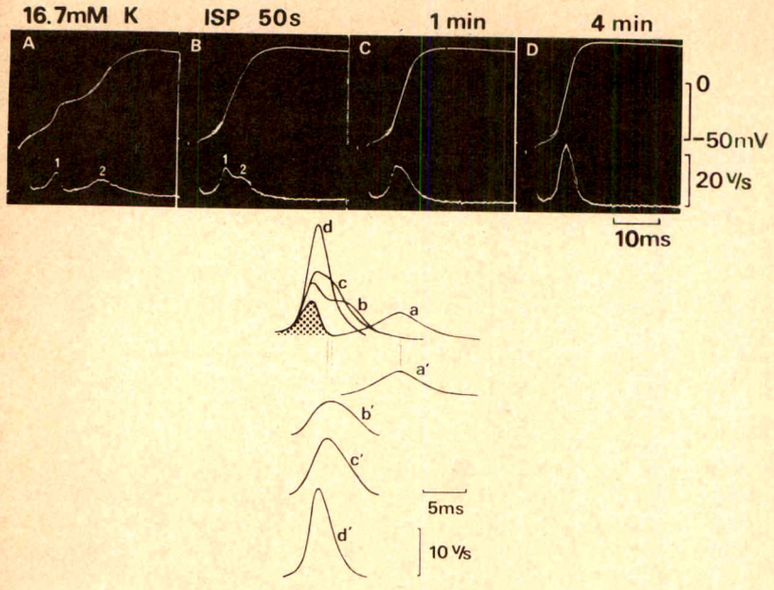

FIGURE 5. Effects of isoproterenol (0.1 μM) on action potential upstroke and the first derivative in 16.7 mM K^+ Tyrode's solution (**upper panels**). **A,** control. **B, C, and D,** 50 seconds, 1 minute, and 4 minutes after application of isoproterenol, respectively. **Numerals 1 and 2** on the lower tracings correspond to $\dot{V}_{max,fast}$ and $\dot{V}_{max,slow}$ as depicted in Figure 1A. **Lower panels,** magnified tracings of upstroke velocity. Tracings a, b, c, and d correspond to the bottom tracing in panels A, B, C, and D, respectively. Tracings a′, b′, c′, and d′ were obtained by subtracting $\dot{V}_{max,fast}$ in tracing a (**stippled area**) from tracings a, b, c, and d, respectively, to demonstrate the isoproterenol-induced change in $\dot{V}_{max,slow}$. In this scheme, the $\dot{V}_{max,fast}$ was assumed to be constant during application of isoproterenol, although $\dot{V}_{max,fast}$ itself was actually decreased by the drug (see text). Marked separation of upstroke phase with diminished $\dot{V}_{max,fast}$ in panel A is partly due to a faster rate of stimulation (0.5 Hz) (compare with Fig. 6).

Characteristics of residual fast channel-dependent slow conduction: Figure 3, A to C illustrates typical effects of lidocaine on the upstroke of residual fast channel-dependent action potential and the conduction in K^+-enriched media. In both action potentials in each panel, the drug decreased $\dot{V}_{max,fast}$ with no change in $\dot{V}_{max,slow}$ and the conduction time was also increased (Fig. 3, B and C). Eventually the conduction was blocked, immediately after recording Figure 3C (not shown). This effect was completely reversible (Fig. 3D). The changes in $\dot{V}_{max,fast}$, $\dot{V}_{max,slow}$, and the conduction velocity during action of lidocaine were plotted versus time, in a different preparation (Fig. 4A). It is evident that the conduction velocity decreased in parallel with

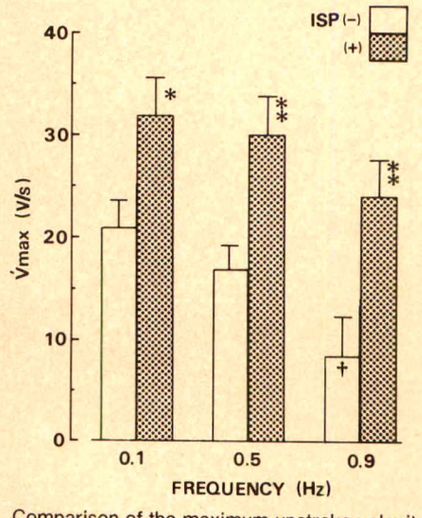

FIGURE 6. Comparison of the maximum upstroke velocity of action potentials in the absence (**open bars**) and presence (**shaded bars**) of isoproterenol (ISP) (0.1 μM) at different stimulation rates (0.1, 0.5, and 0.9 Hz) in 5 preparations each. In these experiments, $\dot{V}_{max}$ was expressed as the amplitude of the larger component out of either $\dot{V}_{max,fast}$ or $\dot{V}_{max,slow}$. Accordingly, $\dot{V}_{max}$ in the absence of isoproterenol (**open bars**) denotes $\dot{V}_{max,fast}$, while $\dot{V}_{max}$ in the presence of isoproterenol (**shaded bars**) represents mostly the amplitude of the $\dot{V}_{max,slow}$ because under these conditions $\dot{V}_{max,slow}$ was markedly increased overriding the $\dot{V}_{max,fast}$ (see Fig. 5, C and D) and $\dot{V}_{max,fast}$ itself was depressed by isoproterenol (see text). **Asterisks** denote significant difference from control value (**open bars**) at each stimulation rate (*$p < 0.05$, **$p < 0.01$); **dagger** indicates significant change ($p < 0.05$) from the control value (**open bar**) at 0.1 Hz. Note that in the presence of isoproterenol there was no significant difference in the $\dot{V}_{max}$ among the different frequencies.

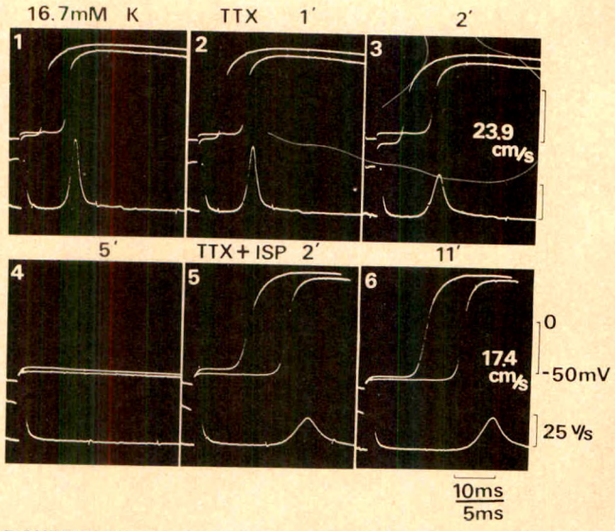

FIGURE 7. Effects of tetrodotoxin (TTX) (1 μM) and isoproterenol (ISP) (0.1 μM) on the action potential upstroke and conduction in 16.7 mM K^+ Tyrode's solution. **1,** control; **2, 3, and 4,** 1, 2, and 5 minutes after application of tetrodotoxin; **5 and 6,** 2 and 11 minutes after the addition of isoproterenol in the continuous presence of tetrodotoxin. In each panel, the bottom tracing represents the first derivative of the proximal (left-side) action potential. In **panel 3,** the microelectrode to some extent extruded from the tissue, thus accounting for a slight decrease in the takeoff potential of the distal fiber (right side), but it returned in panel 4. The **time calibration bar** is 10 ms for action potential tracing and 5 ms for the upstroke velocity in each panel. The interelectrode distance was maintained at 1.6 mm throughout. The conduction velocity was calculated to be 23.9 and 17.4 cm/s in panels 3 and 6, respectively.

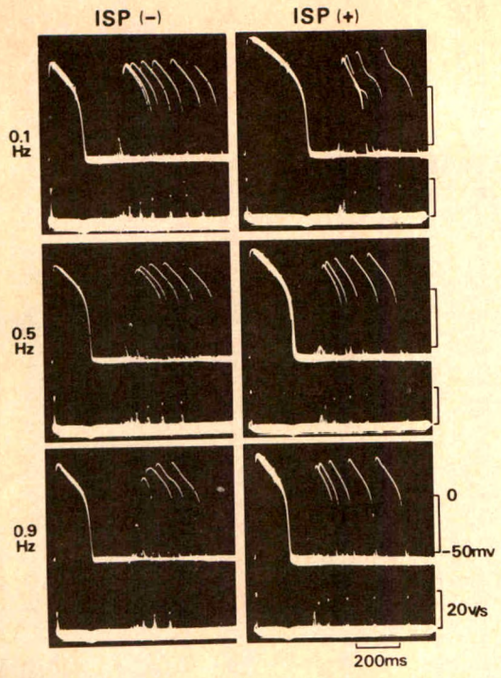

FIGURE 8. Effects of isoproterenol (ISP) (0.1 μM) on repolarization phase in the action potentials elicited by stimulation rates of 0.1, 0.5, and 0.9 Hz in 16.7 m*M* K^+ Tyrode's solution. **Left column,** control records without isoproterenol. **Right column,** effects of isoproterenol. In each panel, the **top tracings** represent the last basic action potential (to the left) and the premature response with variable coupling intervals introduced with every 5 beats of basic stimuli. **Bottom tracings,** first derivative of the action potential.

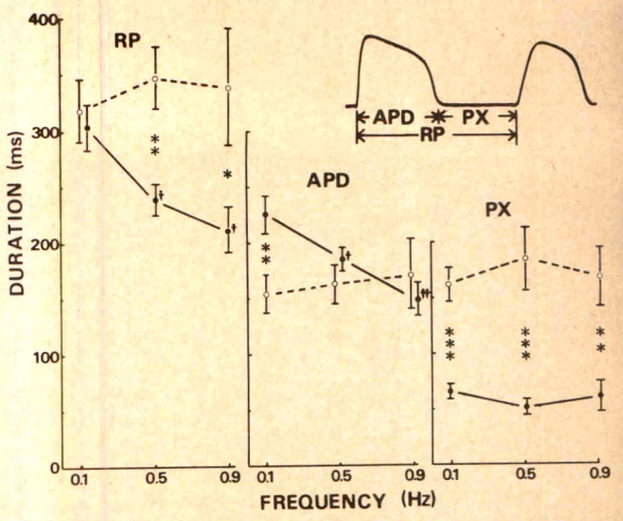

FIGURE 9. Comparison of the durations of postexcitation refractoriness (PX), action potential duration (APD), and effective refractory period (RP) in the absence or presence of isoproterenol (0.1 μM) with different stimulation rates (0.1, 0.5 and 0.9 Hz). **Broken lines** and **open circles** represent the control without isoproterenol; **solid lines and dots** represent effects of isoproterenol. See **inset** for terminology. **Asterisks** denote significant difference from the control value at each stimulation rate (*p <0.05; **p <0.01; ***p <0.001); **daggers** denote significant difference from the duration at 0.1 Hz in the presence of isoproterenol (†p <0.05; ††p <0.01).

the decrease in $\dot{V}_{max,fast}$ while $\dot{V}_{max,slow}$ remained virtually constant until at least 7 minutes after the drug application. Electrical alternation then developed, and there was a prompt decrease in $\dot{V}_{max,slow}$. The alternation continued for about 1 minute before a complete block of the conduction was attained. Similar results were obtained in 2 other preparations.

Conversely, l-verapamil produced little change in $\dot{V}_{max,fast}$ or the conduction time, yet there was a significant decrease in $\dot{V}_{max,slow}$ (Fig. 3, D to F), in keeping with the effects shown in Figure 2, A to C. The time course of the changes during the action of l-verapamil is plotted in Fig. 4B. Comparable results were obtained in 2 other preparations.

Effect of isoproterenol on the upstroke of residual fast channel dependent response: Figure 5A shows an example of the action potential upstroke and the first derivative elicited by a stimulation rate of 0.5 Hz in 16.7 m*M* K^+ concentration, and demonstrates the remarkable step on the way to the peak resulting in a widely split $\dot{V}_{max}$. However the amplitude of $\dot{V}_{max,fast}$ is still larger than that of $\dot{V}_{max,slow}$, indicating that the conduction in this preparation is yet maintained by activation of the residual fast channel. Application of isoproterenol (0.1 μM) quickly shifted the late component ($\dot{V}_{max,slow}$) toward the early one ($\dot{V}_{max,fast}$), as shown in Figure 5B. After 1 minute, both components seemed to fuse (Fig. 5C), and finally $\dot{V}_{max,slow}$ increased considerably, overriding the $\dot{V}_{max,fast}$ (Fig. 5D). At that moment, the step on the upstroke disappeared; the takeoff potentials remained unchanged. The apparent increase in the initial component of split $\dot{V}_{max}$ in Fig. 5B (indicated by "1") was not due to real increase in $\dot{V}_{max,fast}$ but rather to an elevation of the base line produced by both encroachment and increment of the $\dot{V}_{max,slow}$ component (indicated by "2"). The reason was that much lower concentrations of isoproterenol (0.01 to 0.05 μM) always increased $\dot{V}_{max,slow}$ while decreasing $\dot{V}_{max,fast}$ in all 6 preparations tested. Thus isoproterenol produced separate action on the split $\dot{V}_{max}$, that is, an increase in $\dot{V}_{max,slow}$ while decreasing $\dot{V}_{max,fast}$.

The mode of action of isoproterenol on the upstroke phase differed when the stimulation rate was changed. As shown in Figure 6 (open bars), the maximum upstroke velocity of the action potentials in the absence of isoproterenol ($\dot{V}_{max,fast}$) decreased with increase in the stimulation rate from 0.1 to 0.9 Hz. The addition of isoproterenol (0.1 μM) increased the $\dot{V}_{max}$, the peak of which is now composed of $\dot{V}_{max,slow}$ (see Fig. 5, C and D), in all stimulation rates but the increment tended to be remarkable at the higher stimulation rates.

The findings shown in Figures 5 and 6 suggest that the main channel responsible for the slow conduction in the resting potentials of about −58 mV could be changed from the fast to the slow channel during application of isoproterenol, with a conduction velocity comparable to or even faster than that before the application. Figure 7 shows an example of a change in conduction velocity during which time the contributing channels to the slow conduction were altered from the "residual fast" to the "slow" channel with the application of isoproterenol (0.1 μM). Panel 1 (top tracings)

shows action potential upstroke taken from 2 microelectrodes along the preparation in 16.7 m*M* K^+ media, and the bottom tracing denotes the first derivative of the action potential upstroke proximal to the stimulation electrodes (left-hand upstroke). To obtain the slowest possible conduction velocity due to activation of the residual fast channel, we added tetrodotoxin (1 μM) to the preparation (between panels 1 and 2), and this resulted in a prolongation of the conduction time with decreased $\dot{V}_{max}$ (panels 2 and 3). After 5 minutes of the tetrodotoxin treatment, conduction of the impulse was totally blocked and there was a loss of membrane excitability (panel 4). The conduction velocity measured just before development of the conduction block was calculated to be 23.9 cm/s. The addition of isoproterenol between panels 4 and 5 led to a rapid recovery in the generation of action potentials and the conduction (17.4 cm/s) (panels 5 and 6). It is evident that the slow conduction recorded in Figure 7, panel 3 is mediated by activation of the residual fast channel while the slow conduction in Figure 7, panel 6 is induced by activation of the slow channel, since in the latter situation the fast sodium (Na^+) channel should have been completely inactivated by a combination of increased K^+ concentration (16.7 m*M*) plus tetrodotoxin.

Effects of isoproterenol on repolarization in the residual fast channel dependent response: Figure 8 demonstrates the action potentials elicited at different stimulation frequencies of 0.1, 0.5, and 0.9 Hz followed by premature action potentials, with variable coupling intervals. In the absence of isoproterenol (left column), there was no significant difference in the duration of the action potential among different stimulation rates, and the earliest premature response lagged about 180 ms after the end of phase 3 of the basic action potential, in all stimulation rates. We term this interval of no response in phase 4 *postexcitation refractoriness*, which could be due to increased reactivation time of the fast Na^+ channel produced by partial depolarization.[20] In contrast, during the action of isoproterenol, the action potential duration was prolonged at a low stimulation rate (0.1 Hz) and shortened at a high stimulation rate (0.9 Hz). The action potential duration at the intermediate stimulation rate (0.5 Hz) remained much the same. The postexcitation refractoriness was markedly shortened with all the stimulation rates used. This implies that application of isoproterenol leads to a recovery of several properties characteristic of normal ventricular muscle in a physiologic K^+ concentration, that is, rate-dependent shortening of action potential duration[21] and lack of postexcitation refractoriness,[22] which could have been abolished in K^+-enriched media.

The results obtained from 7 similar experiments are summarized in Figure 9. Isoproterenol significantly shortened postexcitation refractoriness by about 120 ms in all stimulation rates, lengthened the action potential duration at 0.1 Hz, and eventually shortened the effective refractory period (the sum of action potential duration and postexcitation refractoriness) at the rates of 0.5 and 0.9 Hz. In the present experiments, stimulation rates of over 0.9 Hz were not applied systematically as many preparations did not consistently respond to such rapid stimulation in K^+-enriched media.

Discussion

In the present study we found that, in 16.7 m*M* K^+-enriched media, the resting potential of guinea pig ventricular muscle was depolarized to about −58 mV and that the action potential upstroke exhibited a step-like discontinuity on the rising phase which was characterized by 2 distinct components of $\dot{V}_{max}$. The early $\dot{V}_{max,fast}$ component was produced by activation of the residual fast channel, while the late $\dot{V}_{max,slow}$ component was due to activation of the slow channel. The amplitude of the former is about 3 times that of the latter. The conduction velocity in this situation was slow (30 to 35 cm/s) and the impulses were transmitted by activation of the partially inactivated Na^+ channel (fast response) and not by the slow channel (slow response). It is well known that the slow conduction in severely depolarized fibers less than −40 mV is dependent on the activation of slow channel.[9] So far as we know there have been no systematic studies on slow conduction at resting potentials of −50 to −60 mV where the fast sodium channels could be still operating.

Two components of action potential upstroke in the presence and absence of isoproterenol: It has been suggested that the action potential upstroke of frog atrial[23] and ventricular muscle[24] might be composed of 2 essentially different components under physiologic K^+ concentrations. In mammalian cardiac fibers, a step on the upstroke with a bifid $\dot{V}_{max}$ has been reported in the case of the guinea pig ventricle after treatment with tetrodotoxin in normal K^+ concentration.[19] The split $\dot{V}_{max}$ demonstrated in the present study may be accounted for on the same basis of the known phenomena. In guinea pig ventricular muscle, the contour of first derivative of the action potential upstroke appeared sharp and single-peaked in normal K^+ concentration. Conceivably, in mammalian cardiac tissue, the second slow component can be disclosed only when the fast Na^+ channel has been considerably inactivated by either increasing K^+ concentration (this study) or by adding tetrodotoxin.[19] A distinct step on the rising phase was reported also in the case of Purkinje fibers in which the fast channel was depressed by elevating K^+ concentrations.[25] The present results indicate that the first upstroke component in guinea pig ventricular muscle is produced by activation of fast Na^+ channel, while the second component is due to the slow channel (Fig. 3). The lack of depressant action of d,l-verapamil on the $\dot{V}_{max}$ has been reported in ventricular fiber depolarized to between −55 and −60 mV by potassium.[26] In 16.7 m*M* K^+ concentration, the amplitude of $\dot{V}_{max,fast}$ was about 3 times that of $\dot{V}_{max,slow}$, and the conduction velocity correlated with the amplitude of $\dot{V}_{max,fast}$ and never with the $\dot{V}_{max,slow}$ (Fig. 4). These findings suggest that the conduction under this situation is maintained by the activation of fast Na^+ channels, although most would be inactivated due to a reduction in the membrane potential ("residual fast channel").

However, when isoproterenol was added to the per-

fusing media, the ionic channels related to the conduction readily changed from the residual fast to the slow channel but without change in the resting potential. Catecholamines restore the action potentials in atrial muscle[27] and Purkinje fibers,[25,28] in which the fast Na^+ channel had been completely inactivated by increased K^+ concentrations. The mechanism underlying the isoproterenol-induced increase in the $\dot{V}_{max,slow}$ (present study) may be the same.

Conduction velocity in excitable tissue is determined by a variety of factors, both passive and active.[29] In mammalian cardiac tissues, the action potential amplitude and the $\dot{V}_{max}$ were considered the most important factors underlying variation in conduction velocity,[30] when the resting potential was less negative than −70 mV.[31] The present study (Fig. 4) lends support to the idea that the $\dot{V}_{max}$ is the major determinant of conduction velocity, at least in K^+-depolarized fibers.

Effects of lidocaine and verapamil on residual fast channel dependent conduction: Using potassium-sensitive electrodes, Hill and Gettes[2] reported that extracellular K^+ concentrations at the center of the ischemic zone in swine hearts increased to a mean value of 10 m*M* (range 5.5 to 16.3) within 5 to 8 minutes after acute coronary occlusion. Comparable data were also presented by Hirche et al,[3] who found that during a short period of occlusion (within 10 minutes) two thirds of the experimental animals developed ventricular tachyarrhythmias including fibrillation. Similar increases of K^+ concentrations were reported in the case of perfused rabbit hearts in which the septal branch of the left coronary artery was occluded.[32]

Although we used nearly maximal K^+ concentrations (16.7 m*M*) reported to be present in the very early phase of myocardial ischemia (within 10 minutes after occlusion), the conduction always depended on activation of the residual fast channel when the perfusate was devoid of catecholamine. Thus, the reentrant excitation evident in the very early phase of regional ischemia[32] may have been due to the slow conduction and unidirectional block through the depressed fast channel. However, since low pH (6.4) and hypoxia (partial pressure of oxygen <30 mm Hg) influenced both $\dot{V}_{max,fast}$ and $\dot{V}_{max,slow}$ with a resultant decrease in the conduction velocity,[33] the final conclusion on the ionic channels responsible for the reentry in in vivo ischemic hearts should await further study.

In most preparations, the conduction velocity in the absence of isoproterenol ranged from 30 to 35 cm/s, under conditions of 16.7 m*M* K^+ concentration (Fig. 4). This degree of conduction velocity appeared slow enough for the maintenance of reentrant arrhythmias in porcine and canine hearts.[34] In that study complete circus movement was convincingly demonstrated along the circle with a diameter of approximately 1 to 2 cm and a revolution time of approximately 120 to 170 ms, thus implying that the calculated conduction velocity could be between 20 and 50 cm/s.

The conduction velocity decreased still further in the presence of a fast channel blocker such as lidocaine or tetrodotoxin, down to about 20 cm/s just before complete conduction block ensued (Fig. 3, 4, and 7). Such marked depressant action of lidocaine on the depolarized ventricular muscle may be explained by a shift of the steady-state $\dot{V}_{max}$-E_m relationship in a hyperpolarizing direction, or the slowed recovery kinetics of $\dot{V}_{max}$ by the drug, or both.[35] However, lidocaine also increases the time-independent outward K^+ current (i_{K1})[36] and reduces the tetrodotoxin-sensitive "window" current[37] in Purkinje fibers. The increase in i_{K1} may decrease the conduction velocity through a reduction in the membrane resistance (shortening of length constant). However, this effect seems to have less importance, if any, since we measured the conduction velocity in high K^+ media in which the membrane resistance should have already been very low.

In the Purkinje fibers, Brennan et al[25] found that lidocaine at a concentration of 5 and 20 μg/ml reduced $\dot{V}_{max}$ and conduction velocity of "depressed fast response action potentials" in which the resting potentials were depolarized to about −60 mV by elevating K^+ concentrations. In contrast, the drug had little or no effect on the slow response elicited in a Na^+-free, Ca^{2+}-rich solution or a high K^+ solution containing norepinephrine. Their findings closely resemble our observations in the ventricular muscle, although they did not direct particular attention to the splitting of $\dot{V}_{max}$ and did not calculate the actual conduction velocity.

Modification of the residual fast channel dependent response by isoproterenol and clinical implication: After complete block of the residual fast channel dependent slow conduction by tetrodotoxin, the addition of isoproterenol reproduced the conduction with a similar conduction velocity (Fig. 7). Theoretically, the latter conduction must depend solely on an activation of the slow channel.[9,25] Therefore, it seems likely that there is no discernible difference between the minimum conduction velocity due to fast channel activation and the maximum conduction velocity due to activation of the catecholamine-enhanced slow channel. If such is indeed the case, the dominant channel responsible for slow conduction and unidirectional block in the reentrant pathway may be changed from the residual fast channel to the slow channel or vice versa without change in conduction velocity when local concentrations of catecholamine are altered. This could happen in a patient with acute myocardial infarction in which sympathetic tone increased transiently.[8]

Although there are no available reports on local differences in catecholamine concentration within the ischemic myocardium, significant differences in the norepinephrine content have been reported in the canine left ventricle under control conditions.[7] Should the local concentrations of catecholamine not be homogeneous within the ischemic tissue, the likelihood of reentrant excitation may alter according to the heart rate, because with relatively rapid rates (≥0.5 Hz), the effective refractory period at a site of high norepinephrine concentration should be shorter than that in a low concentration (Fig. 9). This may result in a nonuniform recovery of excitability, one of the important factors in initiation and maintenance of ventricular tachyarrhythmias.[34]

Vessel Wall Arachidonate Metabolism After Angioplasty: Possible Mediators of Postangioplasty Vasospasm

ANDREW CRAGG, MD, STANLEY EINZIG, MD, PhD,
WILFRIDO CASTANEDA-ZUNIGA, MD, KURT AMPLATZ, MD,
JAMES G. WHITE, MD, and GUNDU H.R. RAO, PhD

The mechanism of postangioplasty vasospasm is uncertain. It was postulated that a reduction in vasodilator prostaglandin I_2 (PGI_2) or prostaglandin E_2 (PGE_2) or an increase in vasoconstrictor hydroperoxy acids might contribute to spasm of a dilated artery. Twelve mongrel dogs were anesthetized, intubated, and mechanically ventilated. Heart rate and aortic pressures were continuously monitored and arterial blood gases maintained within physiologic limits. A single carotid artery was dilated in each animal (4 atm × 1 minute × 3) using nonexpandable polyethylene balloon catheters with inflated balloon diameters 50 to 100% larger than the internal arterial lumen. The opposite carotid artery served as a control. In 4 animals, aspirin (10 mg/kg, intravenously) was injected 30 minutes before dilation. Sixty minutes after dilation, animals were heparinized and the carotid arteries carefully removed. The in vitro conversion of carbon-14(^{14}C)-arachidonic acid (AA) to 6-keto $PGF_{1\alpha}$ (PGI_2), PGE_2, and 12L-hydroxy-5,8,10,14-eicosatetraenoic acid (HETE) was determined using thin-layer radiochromatography. Angioplasty caused a 70% decrease in vessel wall PGI_2 production and a 44% decrease in PGE_2 production ($n = 4$, $p < 0.05$). Reductions in in vitro conversion of ^{14}C-AA to PGI_2 and PGE_2 induced by angioplasty were comparable to that produced by cyclooxygenase inhibition with aspirin. Angioplasty, in addition, caused a 104% increase in vessel wall HETE production ($n = 4$, $p < 0.05$). Therefore, angioplasty results in a local derangement of AA metabolism characterized by decreases in vasodilator prostaglandins and increases in vasoconstrictor hydroperoxy acids. These local changes may contribute, in part, to sudden arterial occlusion after angioplasty.

Vasospasm associated with coronary angiography and transluminal angioplasty is a serious complication requiring prompt treatment.[1–4] Sudden occlusion of the dilated coronary artery occurs in 3 to 8% of cases, often necessitating emergency coronary artery bypass surgery.[5] The mechanism by which postangioplasty vasospasm occurs is not known.

Angioplasty is known to produce its effect in part by overstretching the arterial media. In this respect, vasospasm after angioplasty is a form of traumatic arterial spasm.[6] Hunter[7] first described the property of vasoconstriction after arterial trauma in 1835. Others[8] have documented reflex vasoconstriction induced by arterial stretching.

Numerous studies have investigated potential mechanisms of vasospasm.[6,9–12] Possible mediators include vasoactive substances such as the prostaglandins (PGI_2 and PGE_2) and hydroperoxy acids produced by the coronary arteries as well as thromboxane A_2 (TxA_2) released during platelet activation.[13–19] Decreased production of vasodilator prostaglandins or increased production of the vasoconstricting hydroperoxy acids by the vessel wall may be associated with vasospasm.[13,14,19]

The prostaglandins PGI_2 and PGE_2, both vasodilators in vivo, are produced in vascular endothelium and medial smooth muscle.[20,21] We postulated that damage to the vessel wall which occurs during angioplasty[22,23] could decrease local prostaglandin production or increase local hydroperoxy acid formation and lead to

vasospasm. To test our hypothesis, we determined the effect of arterial dilation on vessel wall arachidonic acid metabolism in canine carotid arteries.

Methods

Animal preparation: Twelve mongrel dogs weighing 15 to 30 kg were sedated with fentanyl (40 mg/kg, intramuscularly) and droperidol (2 mg/kg, intramuscularly) (Innovar-Vet, Pitman-Moore) and anesthetized with sodium pentobarbital (20 mg/kg, intravenously). The animals were mechanically ventilated with room air (Harvard respirator) and anesthesia was maintained by periodic pentobarbital injections.

Catheterization was accomplished by use of femoral artery cutdown. Aortic pressure was measured using a fluid catheter connected to a Statham P23Db strain gauge and was recorded with a lead II electrocardiogram on a Honeywell (model 1858) multichannel recorder. During the control period and 60 minutes after angioplasty, arterial blood samples were measured for pH, partial pressure of carbon dioxide (PCO_2) and oxygen (PO_2) (Instrumentation Laboratory model 113 analyzer), and hematocrit. Selective carotid angiograms were obtained during the control period and immediately after dilation by the rapid manual injection of 7 ml of 60% meglumine diatrizoate (Hypaque® 60, Winthrop). A single carotid artery in each animal was dilated (4 atm × 1 minute × 3) using nonexpandable polyethylene balloon catheters (Meditech, Watertown, Massachusetts). The inflated balloon diameters were 50 to 100% larger than the internal arterial lumen. The length of each dilated segment ranged from 5 to 10 cm (Fig. 1). Oversized balloons were used to simulate the clinical situation in which significant medial stretching is produced by dilation of the stenotic atherosclerotic artery.[24]

In 4 animals, acetylsalicylic acid (10 mg/kg) prepared as a sodium bicarbonate buffered solution (pH 7.0 to 7.5) was injected slowly 30 minutes before dilation. Samples for serum salicylate levels were drawn during the control period and 60 minutes after aspirin administration. Sixty minutes after dilation, each animal in the study was heparinized (300 units/kg) and both carotid arteries were carefully dissected out. Care was taken to avoid blunt trauma to the carotid arteries during their removal. After dissection, the animals were killed with an overdose of sodium pentobarbital.

Arachidonic acid metabolism: Each carotid artery was divided in vitro into a dilated segment and adjacent segments proximal and distal to the dilated portion. The opposite undilated carotid artery was taken as a control. The fresh specimens were placed in a buffered solution (Hanks' Balanced Salt Solution [HBSS], pH 7.4 containing no Ca^{2+} or Mg^{2+}) and loose adventitia was carefully removed.

In 4 animals, carotid artery 6-keto $PGF_{1\alpha}$ (PGI_2) and PGE_2 production was determined. In 4 other animals, the production of 12-L-hydroperoxy-5,8,10,14-eicosatetraenoic acid

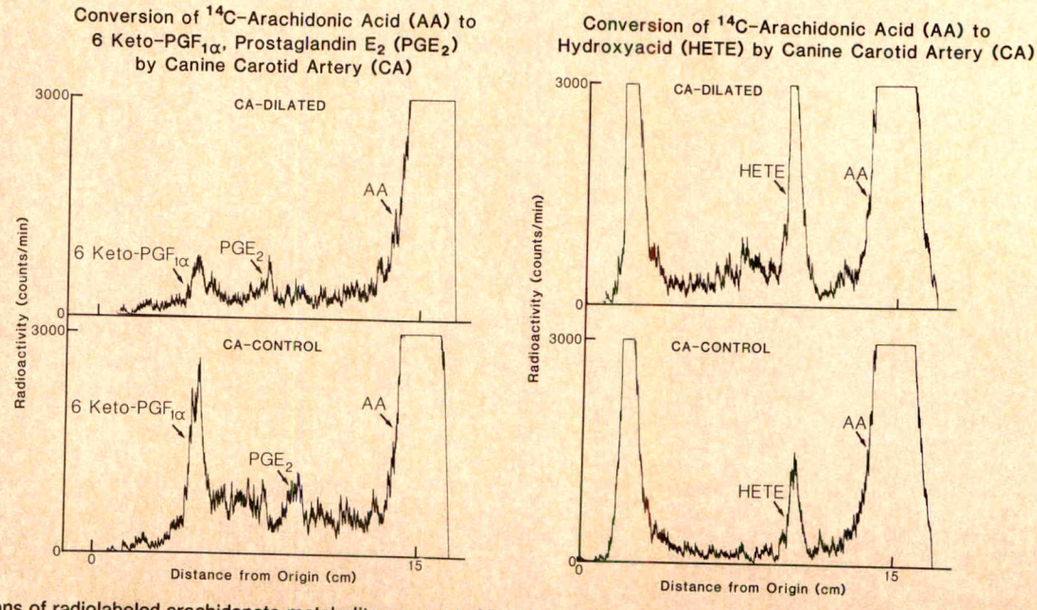

FIGURE 2. Scans of radiolabeled arachidonate metabolites separated by thin layer chromatography. **Left,** peaks for PGI_2 and PGE_2; **right,** HETE for a control and dilated carotid artery. In the dilated artery, PGI_2 and PGE_2 production is decreased while HETE production is augmented.

(HPETE) was determined by measuring its stable hydroxy-metabolite (12-HETE). In the aspirin-treated group, 6-keto $PGF_{1\alpha}$, PGE_2, and HETE production was measured in 2 animals each.

For measurement of arachidonic acid metabolism, each reaction mixture containing approximately 185 ± 35 mg of finely chopped tissue was incubated in 1 ml of regular HBSS (pH 7.4) at 37°C in a shaking waterbath for 60 minutes with 1 μg of labeled arachidonic acid (1-^{14}C-AA; New England Nuclear, Boston, Massachusetts).[25] At the end of the experiment, 1 ml of ethyl acetate was added to each reaction mixture and acidified with 0.5 *M* citric acid to a pH of 3.5. After thorough mixing, the ethyl acetate layer was separated and the reaction mixture was once more extracted with an equal volume of ethyl acetate. Fractions of the organic phase were pooled, concentrated over nitrogen, and saved for further analysis.

Separation of various metabolites: Pooled concentrates were plated on a silica gel G plate. The metabolites PGE_2 and 6-keto-$PGF_{1\alpha}$ were separated with the organic phase of a solvent system comprised of ethyl acetate/2,2,4-trimethyl pentane/acetic acid/water (11:5:2:10 volume/volume).[25] HETE formed by way of the lipoxygenase pathway was separated using a different solvent system consisting of petroleum ether (60 to 70°C)-diethyl ether-acetic acid (60:39:1).[26] Authentic standards of PGE_2 and 6-keto-$PGF_{1\alpha}$ were cochromatographed for identification of the AA metabolites. Radioactivity was monitored with a Berthold radiolabel scanner and quantitation was achieved by separation of the spots containing radioactivity and counting in a Beckman LS3133T scintillation counter. Values for 6-keto $PGF_{1\alpha}$, PGE_2, and HETE are expressed as percent conversion of ^{14}C-AA.

Statistical methods: In vitro vessel wall AA metabolism was analyzed using analysis of variance for repeated measures. Hemodynamic and blood gas data were analyzed using Student's 2-tailed *t* test adjusted for performing multiple tests on correlated data (Bonferroni method).[27] Values are expressed as mean ± standard error (SE). The criterion for statistical significance was $p < 0.05$.

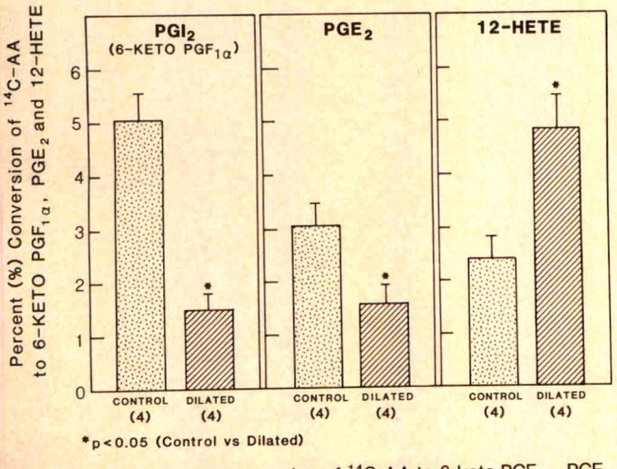

FIGURE 3. Vessel wall conversion of ^{14}C-AA to 6-keto $PGF_{1\alpha}$, PGE_2, and 12-HETE in nonaspirin-treated dogs (mean ± standard error of the mean). The production by the canine carotid artery of the vasodilating prostaglandins, PGI_2, and PGE_2 is significantly reduced after angioplasty. Production of the potent vasoconstrictor 12L-hydroperoxy-5,8,10,14-eicosatetraenoic acid (HPETE) is significantly increased by angioplasty. Note: 12-HPETE is determined by measuring its stable hydroxy-metabolite (12-HETE).

Results

Arachidonic acid metabolism: Figure 2 depicts an original scan of the radiolabeled AA metabolites separated on thin layer plates. Values for percent conversion of ^{14}C-AA to 6-keto $PGF_{1\alpha}$ (PGI_2), PGE_2, and 12-HETE are shown in Table I. Angioplasty caused a significant decrease in vessel wall PGI_2 (70 ± 6%) and PGE_2 (43 ± 14%) production ($p < 0.05$) relative to control (Fig. 3). At the same time, vessel wall HPETE production was significantly elevated (104 ± 13%) compared with control values ($p < 0.01$).

The reduction in PGI_2 and PGE_2 production after angioplasty was comparable to that produced by cyclooxygenase inhibition with aspirin. In aspirin-treated animals, conversion of ^{14}C-AA to 6-keto $PGF_{1\alpha}$ and PGE_2 in the undilated artery was 1.30 and 1.86%, respectively (n = 2). In the dilated artery, values for 6-keto $PGF_{1\alpha}$ and PGE_2 were 0.86 and 1.17%, respectively (n = 2). Control vessel wall HETE production in aspirin-treated animals was 0.89%. In the dilated artery, HETE production was 2.20% (Table II).

Before aspirin administration, serum salicylate levels in aspirin-treated animals (n = 4) were all <2 mg/100 ml, that is, below the sensitivity of our laboratory. The

mean salicylate level 60 minutes after aspirin administration was increased to 3.8 (3.0 to 4.2) mg/100 ml ($p < 0.05$).

Hemodynamic characteristics: No differences were noted between the hemodynamic values from the aspirin and nonaspirin treated groups; therefore, the values from both groups were combined. Mean aortic pressure (97 ± 5 mm Hg), heart rate (113 ± 10 beats/min), PO_2 (97 ± 6 mm Hg), PCO_2 (34 ± 3 mm Hg), pH (7.43 ± 0.02), and hematocrit (41 ± 2%) were maintained within physiologic limits (n = 12). No significant differences were noted 60 minutes after angioplasty, with the exception of aortic pressure which was increased to 118 ± 7 mm Hg ($p < 0.05$).

Discussion

Arterial tone is regulated by a complex combination of neural and humoral factors. Among the humoral mediators of vascular tone are substances such as norepinephrine, adenosine, bradykinin, and prostaglandins which cause either contraction or relaxation of vascular smooth muscle. In recent years, it has been suggested that the prostaglandin endoperoxides and thromboxanes play a significant role in modulating arterial tone, particularly in the coronary circulation.[28] Decreased levels of the vasodilators, PGI_2, PGE_2, and/or PGE_1 or increased levels of vasoconstricting substances such as TxA_2 could be responsible in part for both traumatic arterial spasm and vasospastic angina. PGI_2 and PGE_1 have been used, in fact, to treat certain forms of vasospasm.[29,30]

However, in addition to the well-established pathways of prostaglandin formation, another more recently discovered enzyme—lipoxygenase—has been shown to convert arachidonic acid to various hydroperoxy acids which may have vasoregulatory effects: 12-HPETE produced in the vessel wall[16] has been shown to constrict coronary arteries[17] and rabbit aortic strips[18] and, thus, may contribute to vasospasm. In addition, HPETE inhibits the production of the vasodilator PGI_2.[31]

In our study, PGI_2 and PGE_2 production were significantly decreased in the dilated artery. The decrease in prostaglandin activity was similar to that produced by cyclooxygenase inhibition with aspirin. Aspirin in doses >5 mg/kg may produce vasoconstriction by decreasing PGI_2 production, enhancing platelet accumulation, or both.[32] Endothelial denudation after angioplasty may produce the same effect, that is, decreased PGI_2 production and increased platelet aggregation onto the injured artery with release of thromboxane from platelet thrombi.[30] These factors could contribute to sudden closure of the dilated artery after angioplasty, due either to platelet accumulation or vasospasm.

We found local vessel wall HPETE production to be significantly elevated after angioplasty. Since the vasoconstrictive properties of HPETE are well established, it is not unreasonable to speculate that lipoxygenase products may contribute to vasospasm. The mechanism, however, by which angioplasty causes such a large increase in HPETE production is not clear. It is possible that angioplasty, by denuding the vascular endothelium, removes the major site of PGI_2 production while leaving less affected components of the vessel wall which preferentially metabolize arachidonic acid by way of the lipoxygenase pathway. Figure 4 proposes 1 sequence of events by which vasospasm may be produced after angioplasty.

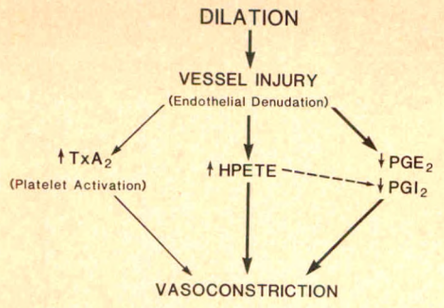

FIGURE 4. Possible mechanism of vasospasm after angioplasty. Arterial dilation which is characterized by medial overstretching and endothelial denudation results in decreased production of the vasodilating prostaglandins PGI_2 and PGE_2 and increased production of the vasoconstrictor hydroperoxy eicosatetraenoic acid (HPETE). HPETE, in turn, further inhibits PGI_2 production. In addition, platelets accumulating at the site of dilation may release thromboxane A_2 (TxA_2), another potent vasoconstrictor.

We also noted in our study that values for PGI_2, PGE_2, and HPETE in the arterial segment adjacent to the dilated portion were generally intermediate between those of the dilated and opposite control artery. The reason for this is not known. It is possible that angioplasty may alter arterial metabolism over a large segment so that the same factors producing local derangement of arachidonic acid metabolism may produce an identical though less intense response remote from the dilation site. It is possible that the hypertonic contrast media used during angiography could affect endothelial cell function and, thus, prostaglandin production. In our study, however, angiograms of the opposite undilated artery were also obtained in 4 animals without altering vessel wall arachidonate metabolism. Furthermore, the small volumes (7 ml) of contrast media used in our study were rapidly diluted by arterial flow.

Aspirin in a dose of 10 mg/kg caused an approximately 50% decrease in vessel wall HETE generation in both control and dilated arteries. The relative increase in HETE production in the dilated artery was preserved, however. While low doses of aspirin (5 mg/kg) do increase HETE production by selectively inhibiting cyclooxygenase, our findings are consistent with other studies which have shown that larger aspirin doses (5 mM = 30 mg/kg) produce peroxidase inhibition as well,[33] resulting in decreased HETE levels, as was observed in our study.

This study has focused on just some of the potential mechanisms for control of vascular tone in damaged arterial tissue. Our results indicate that vascular spasm in some cases may result from reductions in vasodilator prostaglandins or an increase in vasoconstrictor hydroperoxy acids, or both. The extent to which these changes contribute to clinical vasospasm in stenotic

atherosclerotic arteries is unknown. However, since PGI_2 production is known to be reduced in atherosclerotic arteries,[31] even minor reductions may predispose these vessels to spasm. In addition, loss of endothelial cells from the arterial lumen after angioplasty and altered arachidonate metabolism in the vascular wall could convert endothelial dependent endogenous vasodilators (such as acetylcholine and bradykinin) into vasoconstrictors.[34]

Cryosurgery of the Fetal Ductus Arteriosus

PAGE A. W. ANDERSON, MD, FREDERIC B. ASKIN, MD, and MARCOS J. PUPKIN, MD

The effects of cryosurgical treatment of the fetal ductus arteriosus (DA) on the structure and function of the neonatal DA are assessed for the first time. A cryosurgical probe, cooled with nitrous oxide, was used to freeze the wall of the DA in 5 fetal lambs. Six fetal lambs were used as control animals. After birth, all the cryosurgically treated lambs had a patent DA whereas all the control lambs had a closed DA. Only the cryosurgically treated group had these histologic findings: calcific deposits, necrosis, and focal ganglion cell necrosis in the outer one third to two thirds of the media with a decrease or loss of muscle cells and elastic fibers. This study suggests the feasibility of developing a cryosurgical approach for maintaining patency of the DA.

Persistent patency of the ductus arteriosus (DA) may be lifesaving in infants with certain forms of congenital heart disease.[1–3] The only available technique that results in persistent DA patency for a period of months is formalin infiltration of the wall.[1] Although often successful, the desired effect may not be achieved or may disappear within weeks. This study examines for the first time how freezing the fetal DA affects the morphology and the closure of the neonatal DA. Cryosurgery of large arteries and the aorta has not been associated with any complications.[5,6] We used a cryoprobe that had been successful in inducing atrioventricular block and interrupting accessory pathways.[7,8] The fetal lamb was chosen because (1) the effects of DA formalin infiltration were explored initially in the lamb, and (2) patency of the fetal DA is a normal physiologic condition. The lamb is able to recover from surgery before the potentially devastating hemodynamic effects of a widely patent DA are superimposed on the normal neonatal circulation.

Methods

Surgical preparation: Eleven mixed-breed ewes with age-dated pregnancies (5 in the cryosurgically treated group and 6 in the control group) were anesthetized with intravenous ketamine (1 to 4 mg/ml). The uterus was exposed through a low midline abdominal incision, a hysterotomy was made over the fetal left lateral chest, and a thoracotomy performed through the third intercostal space. The parietal pericardium was opened, and using blunt dissection the DA was exposed from its origin at the left main pulmonary artery to its insertion in the descending aorta.

The cryosurgical handheld tool (Frigitronics, Shelton, Connecticut) was cooled by expansion of nitrous oxide within the probe tip. The instrument had an insulated handle and a probe that was 4.3 cm long and ended in a flat circular tip 5 mm in diameter. In both the cryosurgically treated group and the control group, the tip was held for 90 seconds against the DA and then moved to an adjoining area. This procedure was repeated until the entire surface of the exposed DA, from the main pulmonary artery to the aorta, had been covered by these overlapping circles. In the cryosurgically treated group the tip was held at −60°C for the 90 second period. A 1 to 1.5 mm edge of frost extended over the surface of the DA beyond the edge of the probe and then disappeared when the tip was returned to room temperature. Although the depth of the wall subjected to freezing was unknown, the tip was frozen to the surface and could not be removed until the temperature was increased. The shape of the available probe would only allow treatment of the exposed DA surfaces. The period of treatment lasted approximately 20 to 25 minutes before the incisions were closed and anesthesia was discontinued. The subsequent care of the 2 groups of ewes was the same.

Cardiac catheterization: Three cryosurgically treated lambs, were catheterized at the following ages: 3 hours; 3 days; and 1 lamb at 4, 14, and 93 days of age. One control lamb underwent cardiac catheterization on the third day of age. Shunting through the DA was estimated with use of Fick and indocyanine green dye techniques. Hypaque (1 to 1.25 ml/kg) was used for the aortogram.

Necropsy: The lambs were killed using intravenous ketamine (100 mg/kg). In the cryosurgically treated group, 2 died in the first 2 hours of life. The others were killed at 6 hours, 5 days, and 93 days of age. In the control group, 2 were killed at 3 hours of age, and the others were killed at 4 hours, 1, 3, and 5 days of age. The ascending and transverse aortic arch, pulmonary trunk, DA, and descending aorta were removed, fixed

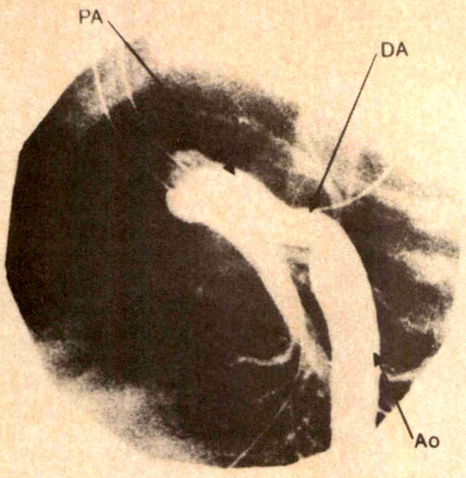

FIGURE 1. Aortogram of cryosurgically treated lamb (see text). The site of injection was the descending aorta (Ao). The main pulmonary artery (PA) and ductus arteriosus (DA) are well filled.

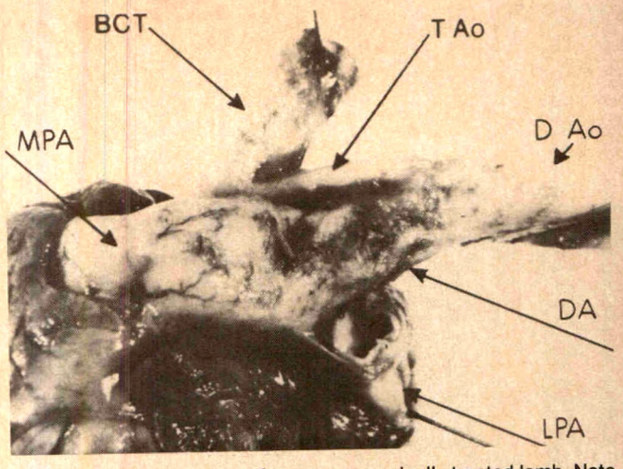

FIGURE 2. Gross specimen from a cryosurgically treated lamb. Note the appearance of the ductus arteriosus (DA), (see text). BCT = brachiocephalic trunk; DAo = descending aorta; LPA = left pulmonary artery; MPA = main pulmonary artery; TAo = transverse aortic arch.

in 10% buffered formalin, and processed for light microscopy. Sections were stained with hematoxylin and eosin, Masson's trichome (for collagen), and by the Verhoeff-van Geison method (for elastic tissue). Two pathologists evaluated them independently.*

Results

Lambs: The cryosurgically treated lambs were operated on at gestational ages ranging from 115 to 135 days of age (127 ± 8, mean ± 1 standard deviation). The control lambs were operated on at ages ranging from 121 to 134 days (mean 128 ± 5). The cryosurgically treated lambs were delivered 17 ± 9 days after surgery. The interval for the control group was 16 ± 5 days. The mean gestational age at delivery of the cryosurgically treated group was 145 ± 4 days and for the control group 144 ± 2 days. The mean birth weight of the cryosurgically treated group was 3.8 ± 0.8 kg and that of the control group was 3.4 ± 0.6 kg. No statistical differences between the groups were found.

Cardiac catheterization: *Cryosurgically treated group:* The 3-hour-old lamb had marked tachypnea and tachycardia. Right ventricular pressure was systemic (70 mm Hg) and the end-diastolic pressure ranged from 10 to 20 mm Hg. The aortogram demonstrated a large amount of left-to-right shunting through a widely patent DA. The 3-day-old lamb had a right ventricular pressure ranging from one third to one half systemic with a 40% left-to-right shunt. An aortogram demonstrated a patent DA.

The third lamb was catheterized 3 times. The first 2 catheterizations demonstrated pulmonary arterial pressure to be 80% of systemic and a 65% left-to-right shunt. The aortograms demonstrated a patent DA (Fig. 1). The third catheterization, at 93 days of age, demonstrated no DA shunting.

Control group: The 3-day-old lamb had no DA shunting. Necropsy confirmed closure of the DA.

*Malouf, N. N., Memorial Hospital, Chapel Hill, North Carolina.

Pathologic findings: *Gross:* In the cryosurgically treated group (Fig. 2) the DA surface was irregular. The wall was thick and hard and on sectioning was gritty. No control animal had these characteristics. The DA was closed in all control lambs. In contrast, 4 animals in the cryosurgically treated group had a patent DA, except for the lamb whose DA was patent at catheterization on the 4th and 14th days of age (see foregoing) but closed at 93 days of age.

Microscopic study: Control group: The DA showed a regular parallel array of circular smooth muscle bundles separated by elastic fibers in the myxoid stroma (Fig. 3). No abnormalities or cellular "cushions" were seen in the intima. The lumen was seen only as a small elongated slit. Longitudinal smooth muscle bundles were irregularly located in the outer one third of the media.

Cryosurgical group: An extensive deposition of calcium, in the form of shards, granules, and irregular plates, was present in the outer one half to one third of the media (Fig. 4). Small foci of bland necrosis were occasionally seen. No evidence of acute inflammation was present. A sparse chronic inflammatory infiltrate, composed predominantly of lymphocytes, was seen in the periphery in 2 cases. In the areas of calcific deposits, a concomitant loss of elastic tissue was found without evidence of an increase in fibrous tissue. An absence or decrease of smooth muscle cells was noted in these areas of necrosis and calcification. Small cellular intimal cushions, composed of longitudinal bundles of smooth muscle cells, were seen as well, but these nodules or cushions did not compromise the lumen. In general, the DA lumen was widely patent, with the lumen averaging approximately one half of the total vessel diameter.

The 1 cryosurgically treated DA that was closed had its lumen filled differently from that of the control DA. Large protuberant intimal smooth muscle bundles appeared to block and distort the lumen into a slit (Fig. 5). Small deposits of fibrinous material were seen in the intima as well. Similar to the closed control DA, prom-

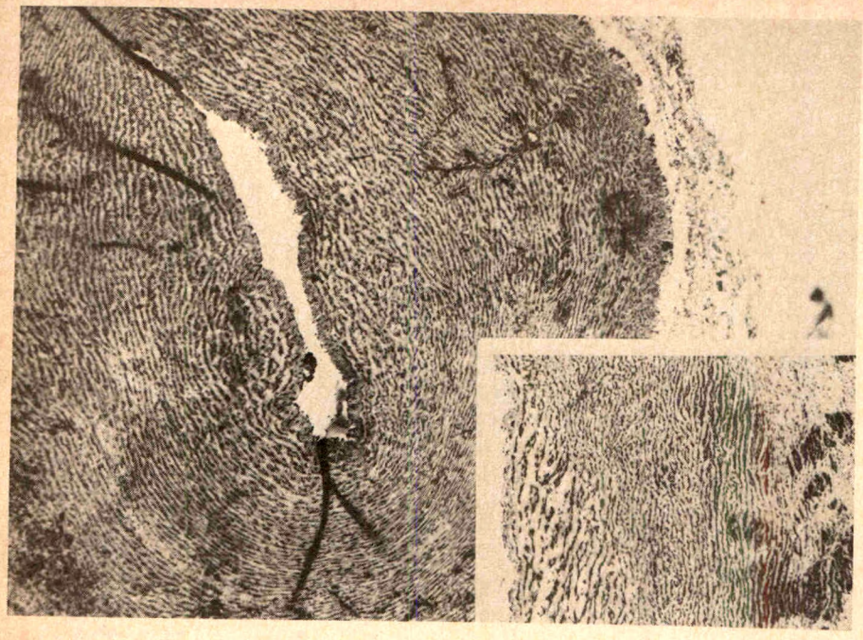

FIGURE 3. Normally closed ductus from a control lamb killed at 3 days of age. The lumen is a narrow slit. Regular parallel arrays of smooth muscle are separated by elastic fibers. Longitudinal bundles of smooth muscle are seen in the periphery of the vessel (**inset**). (Hematoxylin and eosin stain ×125, inset ×200, both reduced 54%.)

inent longitudinal smooth muscle bundles were seen in the outer media. Constriction did not appear to have played a major role in closure.

In 1 cryotreated DA, calcified degenerating adventitial ganglion cells were seen, but ganglia could not be identified in the other treated animals. A variable degree of proliferation of the adventitial small blood vessels was present. The 2 cryosurgically treated animals with the longest intervals between treatment and killing, 31 and 104 days, had an unusual histologic pattern. A marked foreign body giant cell reaction was present in the area of calcific deposits (Fig. 5). The disrupted calcified elastic fibers appeared to be the cause of the reaction.

Discussion

Closure of the DA after birth has been characterized as having 2 components: functional closure and anatomic closure.[9–12] Functional closure is related to constriction of the smooth muscle within the wall and thus obliteration of the lumen. A wide variety of vasoactive substances have been found to modulate this constriction—for example, the prostaglandins, bradykinin, acetylcholine, epinephrine, and norepinephrine.[13–16] In addition, the DA is well innervated with sympathetic nerves whose stimulation could lead to constriction.[15] The second component, anatomic closure, has been related to changes within the wall after constriction, to luminal fibrosis, and to an increase in size of the "inti-

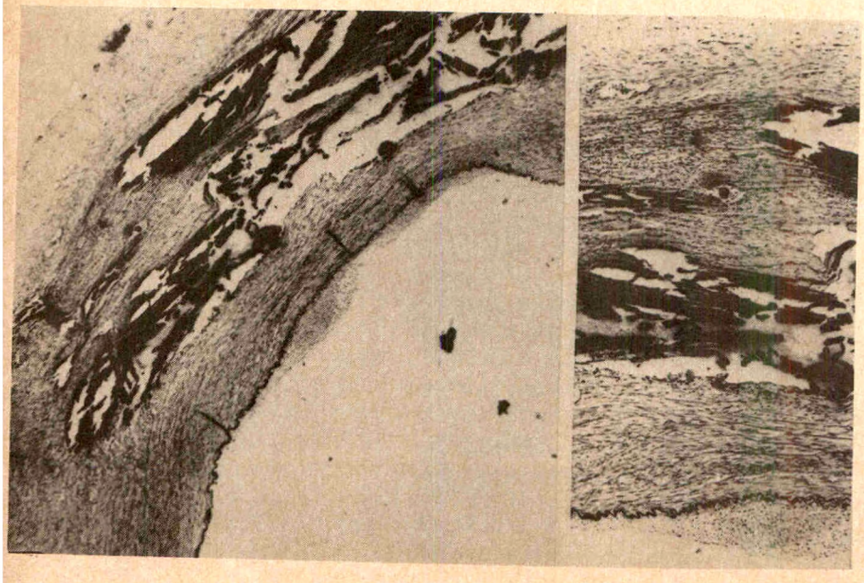

FIGURE 4. Ductus from a cryosurgically treated lamb killed at 6 hours of age. Prominent deposits of calcium are seen in the outer two thirds of the media. The elastic fibers are disrupted in the area of calcification, but no fibrosis is present. A small intimal cushion (**right, bottom**) is seen. No peripheral longitudinal smooth muscle bundles are present. Compare with Figure 3. (Verhoeff-van Gieson elastic stain, **left** ×125, **right** ×300, both reduced 54%.)

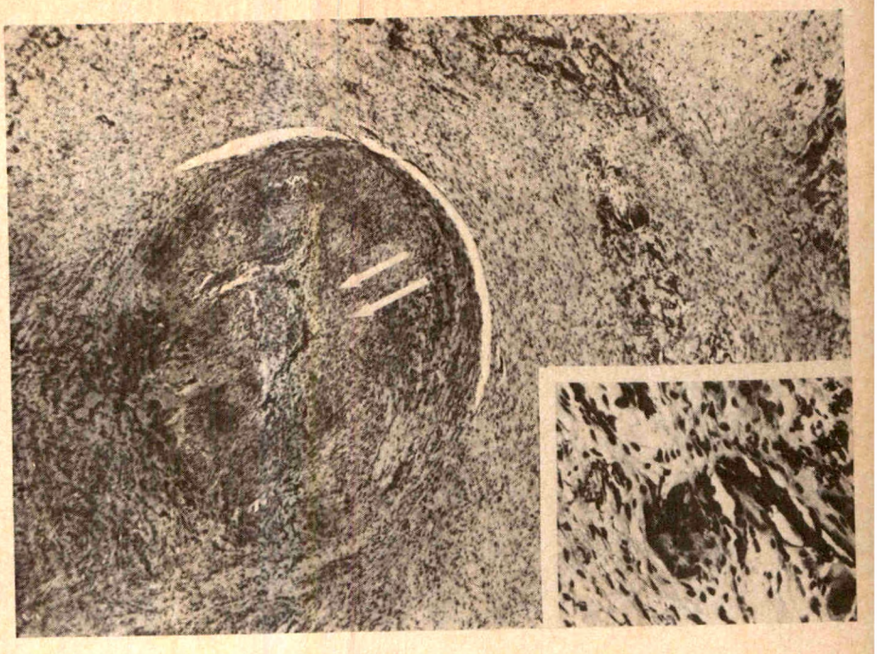

FIGURE 5. Ductus from the cryosurgically treated lamb whose ductus was open during the first 2 weeks of life, and closed by 93 days of age (see text). Calcification is seen as in Figure 4. In addition, the lumen is narrowed by prominent intimal cushions composed of longitudinal smooth muscle bundles (**area of double arrows**). In many areas the disrupted elastic fibers in the media have incited a foreign body giant cell reaction (**inset**). The **crescent-shaped clear area** is an artifact, the obliterated lumen is in the center of the longitudinal muscle bundles (**left of the arrowheads**). (Hematoxylin and eosin stain ×125; inset, Verhoeff-van Geison elastic stain ×350, both reduced 54%.)

mal cushions" that lead to luminal obliteration.[10–12] Because of the great clinical importance of DA patency in certain forms of congenital heart malformations, where closure may be a catastrophic event, approaches have been developed to interfere with these normal processes.[1–3] Formalin infiltration has been useful in interfering with closure, but it is not always successful.[1,4] In a group of 8 lambs that had formalin fetal DA infiltration and were examined after birth, 2 had only a probe patent DA. In humans formalin infiltration has been successful in maintaining DA patency, but in some DA narrowing occurs within weeks of the procedure and is associated with sudden clinical deterioration.[1]

Our decision to evaluate the effects of cryosurgery on normal neonatal DA closure was based in part on the successful and safe use of cryosurgery on other cardiovascular structures.[5–8] Freezing produces death of smooth muscle but does not harm fibrocytes so that a vessel is able to maintain its structure as a blood conduit.[5,6] The temperature of the DA can be lowered with a flat surface. Consequently, the treatment of the entire DA surface would be ultimately possible, whereas a formalin infiltrating needle cannot safely reach the posterior surface.

Fetal DA cryosurgical treatment was successful in preventing normal neonatal DA closure. In 1 lamb the DA closed by 3 months of age, but this lamb had a large left-to-right shunt during its first 2 catheterizations. One possible reason for this later closure is that the entire DA circumference could not be reached by the probe used in this study. This failure was evident in the histologic evaluation: the morphologic changes never extended beyond two thirds of the DA circumference.

Closure of this cryosurgically treated DA did not mimic that of the control group. Each control DA, obtained early in neonatal life, was marked by its constriction (Fig. 3). In contrast, this cryosurgically treated DA lumen was filled with smooth muscle cells located within the intima (compare Fig. 3 and 5). Intimal cushions of smooth muscle cells have been described as a normal human DA structure but were not present in our control group lambs.[10–12] In previous studies of normal DA closure, late obliteration occurred through luminal fibrosis and not through a proliferation of smooth muscle cells.[12] These differences suggest that the mechanisms for normal DA closure were not used in this cryosurgically treated DA.

The histologic effects of cryosurgical treatment of the DA differ from those described in dog carotid and femoral arteries and the rabbit descending aorta. In every cryosurgically treated DA, calcification was a prominent finding, but no increase in fibrous tissue was found. In contrast, fibrosis was a common finding in the dog and rabbit vessels, and calcification was rare in the dog and occurred weeks later in the rabbit. These differences could be related to the DA being treated at −60°C, whereas the other vessels appeared to have been treated at −180°C. Another potential explanation is that the younger the animal, the more likely that cold injury will produce calcific deposits: The dogs were adults, the rabbits were 3 months old, and our lambs were 115 to 135 days of gestation.

The cryosurgical treatment protocol used in this study was based on the protocol that successfully produced cicatrix formation in the dog myocardium.[6] When vessels have been subjected to lower temperature (−180°C) and longer periods of time (10 minutes), freezing of the vessel has occurred and wall-to-wall thrombosis has followed occasionally.[6] We hoped to avoid these complications with our protocol. DA occlusion with frozen blood is unlikely to have occurred because the area of frost extended only 1 to 1.5 mm

beyond the edge of the probe tip and all the lambs survived the surgery. At necropsy no evidence of thrombosis was found.

This study demonstrates that fetal DA cryosurgical treatment interferes with normal neonatal DA closure. Although the mechanisms through which freezing prevents closure are uncertain, a more complete treatment might further interfere with DA closure (for example, a probe can be made that will reach the DA posterior surface). The long-term effects of such cryosurgery on DA closure and the effects of neonatal cryosurgery remain to be assessed. Because of the devastating effects of a widely patent DA on the neonate with an otherwise normal circulation, such future studies might use a model in which the main pulmonary artery is partially or completely obstructed.

Coronary Constriction by Leukotriene C_4, D_4, and E_4 In the Intact Pig Heart

DAVID EZRA, MD, LILLIE M. BOYD, PhD, GIORA FEUERSTEIN, MD, and ROBERT E. GOLDSTEIN, MD

Leukotrienes are naturally occurring vasoactive metabolites of arachidonic acid that increase during inflammatory reactions and anaphylaxis. Coronary constriction and reduced myocardial contractility after leukotriene C_4 and D_4 administration were demonstrated in the isolated guinea pig heart. To explore the effects of leukotrienes in the in situ, blood-perfused heart, we administered leukotrienes C_4, D_4, and E_4 into the coronary artery of the domestic pig.

Increasing doses (0.1, 0.3, 1.0, and 3.0 μg) of leukotrienes C_4, D_4, and E_4 were injected into the left anterior descending coronary artery of 8 open-chest domestic pigs. Significant dose-related reduction in coronary blood flow was observed after each leukotriene administration. Three micrograms of each leukotriene produced the following maximal decreases (mean $\pm$ standard error): $C_4 = 80 \pm 9\%$, $p < 0.001$; $D_4 = 81 \pm 3\%$, $p < 0.001$; $E_4 = 64 \pm 12\%$, $p < 0.005$. In several instances, surface electrograms recorded from the myocardial region exposed to leukotrienes showed signs of focal myocardial ischemia, sometimes accompanied by ventricular arrhythmia. Significant elevation of left ventricular end-diastolic pressure was observed after large doses (1 or 3 μg) of leukotrienes C_4 and D_4. Minimal (5 to 10%) decreases in mean arterial pressure and no change in heart rate were observed after leukotriene injection.

We conclude that leukotrienes C_4, D_4, and E_4 are extremely potent coronary constrictors in the in situ heart. The intensity of response and associated electrocardiographic signs of ischemia suggest that constriction is mainly due to a primary effect on vascular smooth muscle. However, coronary flow reduction may also reflect consequences of a primary negative inotropic action. Leukotrienes may play a significant role in the pathogenesis of a variety of cardiac disorders, particularly those associated with extensive inflammatory changes.

Leukotrienes are a recently identified family of compounds whose potent biologic activity may figure significantly in disease processes. These naturally occurring metabolites of arachidonic acid are produced by lipoxygenase of white blood cells, mast cells, and other cell types. Their production is stimulated by a variety of pathologic circumstances including cell exposure to antigen-antibody complexes, activated complement, and other elements of the inflammatory response. Leukotriene C_4 (LTC_4) and leukotriene D_4 (LTD_4) are potent constrictors of smooth muscle in several different preparations.[1–3] Because leukotrienes are major constituents of slow-reacting substance of anaphylaxis (SRS-A), a principal humoral mediator of adverse events in anaphylaxis, they may be responsible for coronary constriction that has been observed during anaphylactic reactions.[4,5] Vasoconstriction has been demonstrated by the capacity of LTC_4 and LTD_4 to increase systemic vascular resistance in the rat,[6,7] to reduce perfusion of guinea pig skin,[8] and to diminish coronary flow in the isolated, crystalloid-perfused guinea pig heart.[9–11] To explore the possibility that leukotrienes might reduce coronary perfusion in the

intact animal, we measured the effects of intracoronary administration of LTC_4, LTD_4, and LTE_4 in the in situ, blood-perfused hearts of domestic pigs.

Methods

Eight domestic pigs of either sex, aged approximately 10 weeks and weighing 17 to 32 kg, were sedated with ketamine hydrochloride, 20 mg/kg intramuscularly, and anesthetized with pentobarbital sodium, 2 to 4 mg/kg/h intravenously. Animals were ventilated with a Harvard respirator modified to deliver 3 cm of water positive end-expiratory pressure. Ventilatory rate and inspired oxygen concentration were adjusted to maintain partial arterial oxygen pressure at 80 to 120 mm Hg and partial carbon dioxide pressure at 35 to 40 mm Hg. Hematocrit was 25 to 32% (normal for pigs of this age). Catheters filled with heparinized saline solution were placed in the jugular vein and internal mammary artery. The left ventricular cavity was catheterized through the carotid artery. Rectal temperature, mean arterial pressure, left ventricular pressure, and lead II of the standard electrocardiogram were monitored continuously. In addition, a surface electrogram was recorded from the region supplied by the distal left anterior descending coronary artery using a saline-soaked cotton wick electrode. Rectal temperature was maintained at 37.5 to 38.5°C by an external heating pad. A left thoracotomy was performed and the heart suspended in a pericardial cradle. A circumferential electromagnetic flow probe was placed around an exposed proximal portion of the left anterior descending artery and attached to a 501D Carolina square-wave flowmeter. A fine tygon catheter used to administer the leukotriene was introduced into the left anterior descending artery several millimeters distal to the flow probe.[12]

Pure synthetic LTC_4, LTD_4, and LTE_4 dissolved in distilled water (kindly provided by Joshua Rokach, PhD, Merck-Frosst, Dorval, P.Q., Canada) were obtained frozen on dry ice and stored at −70°C. Stock solutions (1 mg/ml) were diluted with heparinized 0.9% saline solution (vehicle). On each study day, leukotriene concentration in stock solutions was confirmed by spectrometry at 280 nm. Intracoronary injection of 0.1 ml leukotriene solution was followed by a 0.5 ml vehicle flush. The pH of all injected solutions was 7.15 to 7.20. After baseline recording of heart rate, mean arterial pressure, left ventricular pressure, and mean coronary blood flow, a 0.5 ml bolus of the vehicle was injected into the left anterior descending artery. Fifteen minutes later, individual bolus doses of leukotrienes were delivered within 3 seconds in ascending order: 0.1, 0.3, 1.0, and 3.0 μg. After each bolus, monitoring of all variables continued for 10 to 15 minutes or until return to baseline values, whichever was longer. The order of leukotriene administration was interchanged during successive studies and had no effect on the results. Animals were killed with additional pentobarbital sodium and potassium chloride. A paired data analysis using Student's *t* test was applied to evaluate leukotriene effects. Results are reported as mean ± standard error of the mean. Correlation between coronary blood flow and left ventricular end-diastolic pressure was tested by linear regression.

Results

Before leukotriene administration, mean coronary blood flow was 46 ± 5 ml/min. Table I shows the percent decrease in coronary blood flow after intracoronary injection of the leukotrienes. Each leukotriene caused significant reduction of coronary blood flow at the smallest dose tested. The maximal change in coronary blood flow after the smallest dose of LTC_4, LTD_4, and LTE_4 occurred 7 ± 2, 10 ± 2, and 9 ± 2 seconds, respectively, after leukotriene injection, and recovery to baseline level was completed within 2 to 3 minutes. Larger doses of each leukotriene produced profound, transient reduction in coronary blood flow. Total arrest of flow (coronary blood flow ≤1 ml/min) was observed after 9 such injections. The maximal change in coronary blood flow after the largest dose of LTC_4, LTD_4, and LTE_4 occurred 18 ± 2, 21 ± 4, and 8 ± 1 seconds, respectively, after the leukotriene injection, and recovery was completed within 3 to 4 minutes. Saline injection had no consistent effect on coronary blood flow, left ventricular end-diastolic pressure, mean arterial pressure, or heart rate.

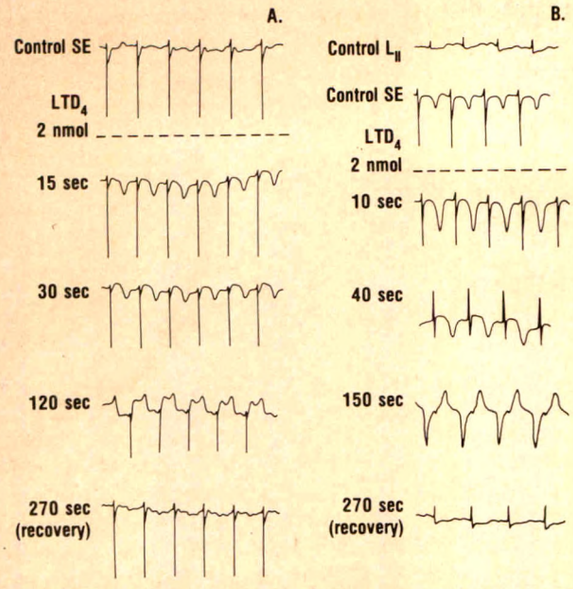

FIGURE 1. Focal electrocardiographic changes after intracoronary injection of 2 nmol (1 μg) of LTD_4. **A,** surface electrogram (SE) recorded from the region perfused by the left anterior descending coronary artery distal to the catheter entry site. Recordings were made before LTD_4 administration (control) and after administration at 15 seconds (T-wave inversion), 30 seconds (S-T elevation), 120 seconds (severe S-T elevation), and 270 seconds (recovery). **B,** the conventional lead II and SE are shown with normal sinus rhythm before LTD_4 administration, ischemic changes in SE 10 and 40 seconds after LTD_4 administration, and ventricular rhythm in SE after 150 seconds. Normal sinus rhythm in lead II was recorded after 270 seconds (recovery).

kotriene. After 1.0 and 3.0 μg of LTC_4 and LTD_4, a profound decrease in coronary blood flow was accompanied by a significant elevation in left ventricular end-diastolic pressure and a slight decrease (5 to 10%) in mean arterial pressure at the peak of leukotriene effect. Left ventricular end-diastolic pressure and mean arterial pressure returned to baseline along with recovery of the coronary blood flow. Mean heart rate (pretreatment range 135 to 145 beats/min) remained unchanged after all doses. Linear correlation analysis between the absolute change in coronary blood flow and the absolute change in left ventricular end-diastolic pressure showed no significant correlation.

Figure 1A illustrates signs of ischemia on the surface electrogram when coronary blood flow was reduced by 85% after 1 μg of LTD_4. The changes in T wave and S-T segment rapidly reversed on return of coronary blood flow to baseline. Similar changes occurred in 3 other pigs.

Transient rhythm disturbances were observed in 4 of 8 pigs given 1 or 3 μg of LTC_4 or LTD_4. All arrhythmias were ventricular in origin, occurred immediately after peak hemodynamic effects, and disappeared 3 to 5 minutes later.

Discussion

Our results demonstrate that LTC_4, LTD_4, and LTE_4 each produced a dose-related decrease in coronary blood flow when administered as a bolus into the coronary artery of the pig. Associated hemodynamic findings, particularly at smaller doses, suggest that coronary blood flow decreased in response to a leukotriene-induced increase in coronary vascular resistance rather than a decline in driving pressure across the coronary bed or diminution in duration of diastolic coronary flow. These data support previous results demonstrating leukotriene-mediated vasoconstriction in isolated, crystalloid-perfused hearts.[9–11] One report describes similar results in the in situ sheep heart.[13] The attendant electrocardiographic evidence of local myocardial ischemia in our preparation and the severity of flow decrement imply that coronary constriction was a primary response to leukotrienes rather than a secondary response to reduced myocardial perfusion requirements.

Intracoronary administration of leukotrienes tended to limit effects to a single region of myocardium as well as to maximize direct action of a given dose on coronary flow. The S-T segment elevation and deep symmetrical T-wave inversion in the locally recorded electrocardiogram, the development of ventricular ectopy, the decrease in mean arterial pressure, and the increase in left ventricular end-diastolic pressure transiently occurring with administration of larger doses of the leukotrienes may all be explained as the electrical and mechanical consequences of regional ischemia. Reduction in mean arterial pressure is likely to represent a response to myocardial ischemia rather than a direct action of leukotrienes on the systemic circulation, because intravenous leukotriene administration consistently produces early pressor responses in the rat and guinea pig.[6–8] However, data from isolated hearts suggest a direct toxic influence on mechanical properties of myocardium.[10] In our study the increase in left ventricular end-diastolic pressure was not correlated with the decrease in coronary flow, possibly reflecting negative inotropic effects of leukotrienes not mediated by reduced myocardial perfusion. In some instances, a primary negative inotropic action might contribute to coronary constriction through autoregulatory mechanisms.

The capacity of leukotrienes to reduce coronary flow and cause electrical and mechanical myocardial dysfunction suggests that leukotrienes may play a significant role in the pathogenesis of a variety of cardiac disorders, particularly those associated with extensive release of SRS-A. For example, anaphylaxis is associated with contractile depression, arrhythmias, reduced coronary flow, and abundant release of SRS-A.[14,15] Immune complexes can cause the heart to release large quantities of SRS-A, demonstrating the capacity of cardiac tissues to produce leukotrienes in abundance when stimulated appropriately. Because leukotrienes can produce such extreme reduction in coronary flow, even in subnanomole quantities, the cardiac abnormalities known to accompany anaphylaxis may reflect myocardial ischemia due to leukotriene action as well as the effects of histamine and other vasoactive or cardiodepressor factors.[14,15]

Leukotrienes may exert a much broader influence in the pathogenesis of cardiac disorders. Because leukotrienes are produced by inflammatory cells from ubiq-

uitous constituents, their potent coronary constrictor activity constitutes a novel and potentially important link between inflammatory processes and increased coronary vascular resistance. Coronary vessel tone may be an important factor in the precipitation and perpetuation of ischemic events with variant angina, unstable angina, and acute myocardial infarction.[16] Local or systemic release of leukotrienes in response to tissue injury might contribute significantly to coronary spasm, stasis of flow, and intravascular thrombosis. Thrombus-promoting action may be potentiated by leukotriene-induced release of thromboxane A_2.[17] LTC_4 and LTD_4 also promote tissue edema[18] that may further diminish coronary perfusion and augment cellular injury. Leukotriene-induced coronary constriction may add significantly to a mechanical plugging effect of white blood cells in ischemic myocardium.[19] Under these circumstances, the use of specific antagonists of leukotriene may offer a significant and possibly synergistic therapeutic modality.

The AJC in May 1958

CAROLE A. WARNES, MB, BS, MRCP and WILLIAM C. ROBERTS, MD

This is the first of a new section in the *Journal* which will examine 1 or more articles published in the same month's issue 25 years ago. In contrast to a recent issue (February 1983), the May 1958 AJC was shorter in length, each page was less compact, and each paper was less concise and scientific (Table I). Not a single 1 of the 17 articles in the May 1958 issue contained a p value! Three articles in the May 1958 issue have been selected for comment.

Aortic Stenosis (Paul Wood)

In an 18-page lead article Paul Wood, from London, described clinical features in 250 patients with aortic stenosis (AS) he had seen in a 7-year period. During the same period, he saw 78 patients with "pure rheumatic aortic regurgitation" (AR) and "about 700" with mitral valve disease. In this study Wood excluded patients with "dominant mitral valve disease." The cause of AS in his 250 patients was considered rheumatic in 180, congenital in 54, and unstated in 16. The ages of the 180 rheumatic AS patients ranged from 19 to 79 years (average 46), and 44% had a history of a "rheumatic state." In >90% the degree of AS was considered "severe." Calcific deposits in the aortic valve were observed by radiography in 80% of the patients >30 years of age. The male to female ratio was 2 to 1. Of those patients with any symptoms, angina pectoris was present in 70%, syncope in 33%, and breathlessness in 45%. Wood carefully documented the physical signs of AS, and these observations remain valid. Aortic valvotomy was performed in 80 patients with a 20% mortality: 54% had a good result and 26% an "indifferent" result. Wood wrote: "In conclusion one might say that at the present time aortic valvotomy is too hazardous and too crude an operation to advise it when it is most desirable (just before the onset of symptoms) and frequently too late when impending disaster makes it imperative; nevertheless, the results of skilled surgical treatment far outweighs anything that medicine has to offer."

TABLE I Comparison of 2 Issues of AJC: May 1958 and February 1983

Item	May 1958	February 1983
Number of pages	121	262
Number of lines per column	50	62
Number of letter spaces per line	46	55
Number of papers	17	47
Average number of pages per paper	7	6
Average number of authors per paper	2	5
Maximum number of authors on a paper	5	18
Average number of references per paper	14	22
Number of papers from outside the U.S.	1 (7%)	9 (19%)
Number of papers containing a p value	0	23 (49%)

This study subsequently has been referred to on many occasions. All 250 patients with AS were studied personally by Wood. Despite the excellence of his description of the clinical signs, the paper, in retrospect, has certain deficiencies. His discussion on the etiology of AS appears to have been based entirely on historic information. It is now clear that, for practical purposes, AS has only 3 etiologies: congenital, rheumatic, and degenerative. Although Wood mentioned the congenital and rheumatic etiologies, the criteria for inclusion in either category were not defined. Wood thus adhered to the thinking of the time, that is, that rheumatic heart disease was the major cause of AS and AR, a viewpoint popularized by Karsner and Koletsky. The bicuspid aortic valve was not mentioned in his report, yet today we know that most patients age ≤65 years with AS (with or without AR) unassociated with mitral valve disease have the AS superimposed or a congenitally bicuspid aortic valve. The degenerative or wear-and-tear etiologic concept of AS, likewise, was not considered in 1958. Irrespective of its limitations, this single-authored paper remains a classic on the subject.

Idiopathic Dilated Cardiomyopathy (David H. Spodick* and David Littman)

Spodick and Littman from West Roxbury, Massachusetts, summarized clinical observations in 8 patients with what we now call "idiopathic dilated cardiomyopathy." The 8 patients were seen at a Veterans Administration Hospital during a 9-year period. In their discussion, they mentioned that a "search of the world literature" disclosed 72 reported patients with the iso-

* Currently a member of the AJC's editorial board.

lated finding of "unexplained large heart." This study is a fine review of reported patients with presumed idiopathic dilated cardiomyopathy up to 1958.

Coronary Heart Disease: An Evaluation and Criticism of Present-Day Concepts (Claude S. Beck)

This 6-page editorial by a pioneer of coronary surgery criticizes the complacency of cardiologists for not considering surgery the most definitive form of therapy for this condition. Beck described 4 surgical procedures which might increase myocardial oxygenation: "abrasion of surface of heart and lining of parietal pericardium, a light application of 5% aqueous solution of trichloroacetic acid to the surface of the heart between the coronary arteries, a light sprinkling of powdered asbestos on the surface of the heart, narrowing the coronary sinus to a diameter of 3 mm, application of parietal pericardium and its outside fat to the surface of the heart as a graft." The concept of coronary bypass grafting was mentioned briefly: "We tried to add blood from grafts on the heart including the mammary arteries. We also tried to clean out the coronary arteries and also to place shunts in them. Others are working on these developments. Perhaps something more effective will be developed in the future and this work should be encouraged."

Beck wrote, "The definition of progress is the replacement of wrong ideas by scientific facts . . . . Every age, including our own, knows so much that isn't so."

Program of the College Annual Meeting

The May 1958 issue also included (in 5 pages) the entire program of that year's annual meeting of the American College of Cardiology.

Kent Pathways Visualized in Situ and Removed at Operation

Richard Brodman, MD
John Fisher, MD
Sumi Mitsudo, MD
Soo Gyum Kim, MD
Jeffrey Matos, MD

In 2 patients, left free wall accessory atrioventricular muscle bundles (Kent bundles) were visualized in situ during dissection of the coronary sulcus fat and removed for histologic documentation. Kent pathways, therefore, may be visible if looked for at operation.

There is substantial evidence that the structures removed were Kent pathways: (1) they were found in the location predicted by careful pre- and intraoperative mapping (Fig. 1 and 2); (2) they bridged the atrium and ventricle (Fig. 3 and 4); (3) they consisted of muscle fibers surrounded by epicardial fat (Fig. 5 to 8); and (4) electrophysiologic testing confirmed division of the Kent pathways. Sealy et al[1] found in their review that only 5 of the 21 postmortem specimens had more than 1 strand. The presence of other smaller muscle bundles cannot be excluded as they may have been divided before visualization with the 2.5 power operating loops.

The variable location and number of Kent pathways in the epicardial fat and the sheer presence of fat in the

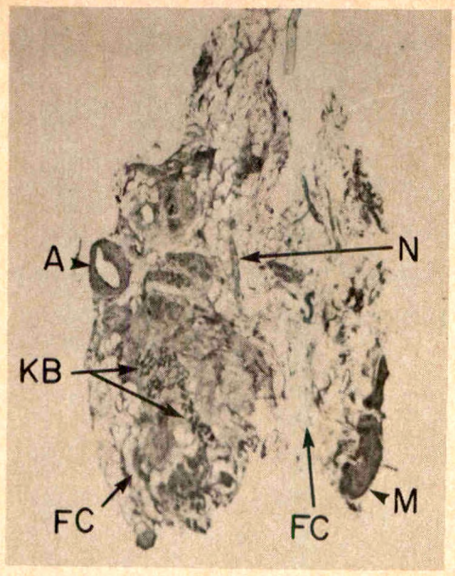

FIGURE 5. Biopsy specimen of tissue removed from the coronary sulcus in Case 1 containing Kent fibers (KB), fat cells (FC), nerve fibers (N), artery (A), and myocardial fibers of left atrium (M). (Hematoxylin and eosin stain; magnification ×25.)

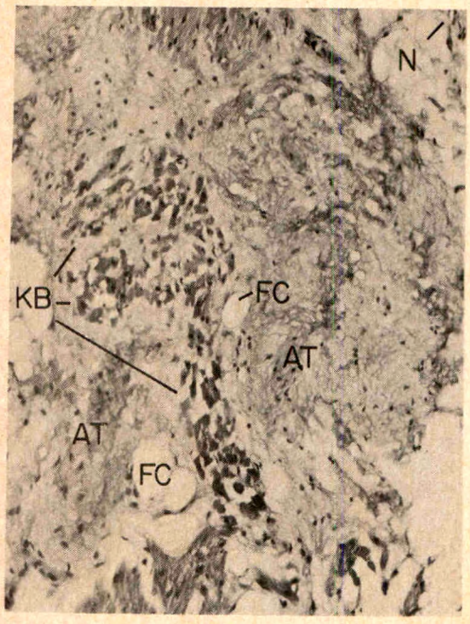

FIGURE 6. Higher power photomicrograph of the Kent fibers (KB) from Case 1 surrounded by fibroadipose tissue (AT and FC) containing nerve fibers (N). (Magnification ×100, reduced 28%.)

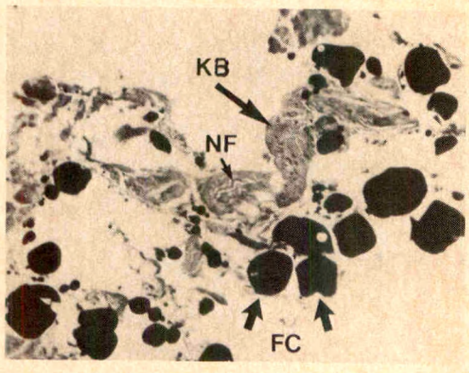

FIGURE 7. Biopsy specimen of tissue removed from the coronary sulcus in Case 2 containing Kent fibers (KB), fat cells (FC), and possibly a nerve fiber (NF). The fat cells are black because this specimen was fixed in glutaraldehyde, postfixed in osmium tetroxide, and then stained with hematoxylin and eosin. (Magnification ×100, reduced 45%.)

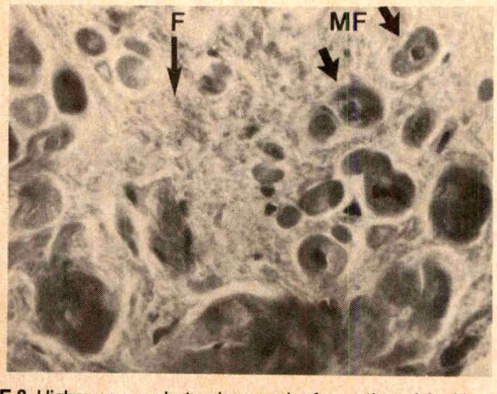

FIGURE 8. Higher power photomicrograph of a portion of the Kent fibers seen in Figure 7, showing marked fibrosis of muscle fibers (F) interspersed with normal muscle fibers (MF). (Magnification × 400, reduced 40%.)

coronary sulcus may make identification difficult. It should, however, be possible to identify a structure with an average widest dimension of 1.8 mm,[1] particularly if magnification currently available in the operating room is used.

Unless these cases prove atypical, the Kent pathway will become visible and divisible, not invisible and divisible. Although visual identification of the bundle of Kent is not a necessary part of the operative procedure for Wolff-Parkinson-White syndrome, removal of a visible bundle of Kent may make in vitro electrophysiologic study possible.

Lipoma of the Mitral Valve and Papillary Muscle

Ramsey Behnam, MB, MRCP
Gordon Williams, MB, MRCP
Leon Gerlis, FRC (Path)
Duncan Walker, MB, FRCS
Olive Scott, MD, FRCP

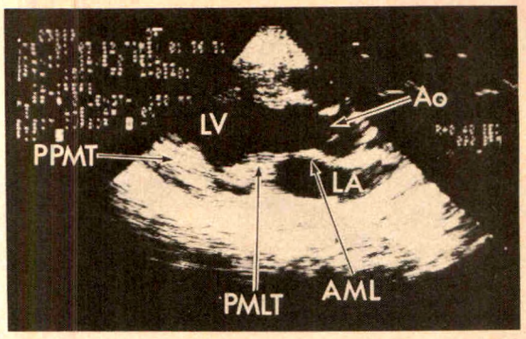

FIGURE 2. Long-axis 2-dimensional echocardiogram of the left ventricle. Two tumor masses are seen, 1 in the posterior mitral leaflet (PMLT) and the other in the posterior papillary muscle (PPMT). AML = anterior mitral leaflet; Ao = aortic root; LA = left atrium; LV = left ventricle.

Mitral valve tumors are rare. This report describes findings in a patient with mitral regurgitation (MR) due to multiple mitral valve lipomas.

An asymptomatic girl presented at age 2 years with signs of MR. The electrocardiogram showed left ventricular (LV) hypertrophy, and a chest radiogram showed an enlarged left atrium but was otherwise normal. At 4 years, cardiac catheterization showed a mean pulmonary capillary wedge pressure of 14 mm Hg with a V wave of 27 mm Hg. The LV cineangiocardiogram showed free MR. No filling defect was seen in the left ventricle, left atrium, or region of the mitral valve. The patient remained asymptomatic; hemoglobin, white blood cell count, and erythrocyte sedimentation rate were normal.

Echocardiography, performed when the patient was 14 years of age with a mechanical sector scanner (Advanced Technical Laboratories, Seattle, Washington, 5 MHz probe), showed a dense mass of echoes arising from the posterior mitral leaflet; it extended anteriorly toward the free edge of the anterior leaflet, from which it was separated by an echo-free space (Fig. 1). The 2-dimensional echocardiogram revealed the presence of 2 tumors, 1 in the posterior mitral leaflet and 1 in the posterior papillary muscle (Fig. 2).

The mitral valve was explored when the patient was 16 years old. The posterior cusp was replaced by a hemispher-

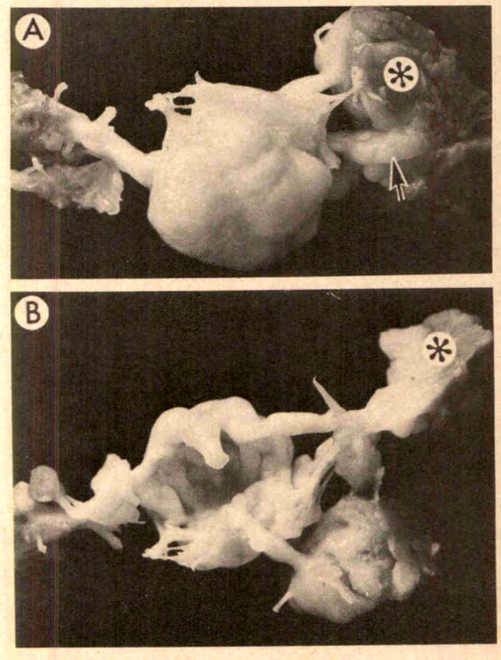

FIGURE 3. A, excised posterior mitral valve cusp, viewed from the atrial aspect, showing the globular tumor replacing most of the free portion. The **asterisk** indicates tumor involvement of a papillary muscle. The **arrow** indicates tumor spread upward into a chorda tendineae. **B,** concave ventricular aspect of the specimen.

From the Department of Paediatric Cardiology, Killingbeck Hospital, Leeds, England. This study was supported by the National Heart Research Fund, England. Manuscript received October 18, 1982; revised manuscript received and accepted December 15, 1982.

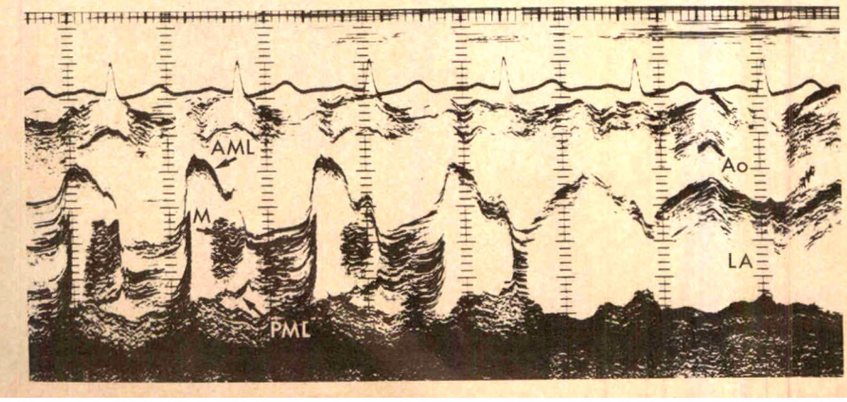

FIGURE 1. M-mode echocardiogram from the left ventricle (LV) to the aorta (Ao). A dense mass of echoes (M) arises from the posterior mitral leaflet (PML). The left atrial cavity (LA) is free of echoes.

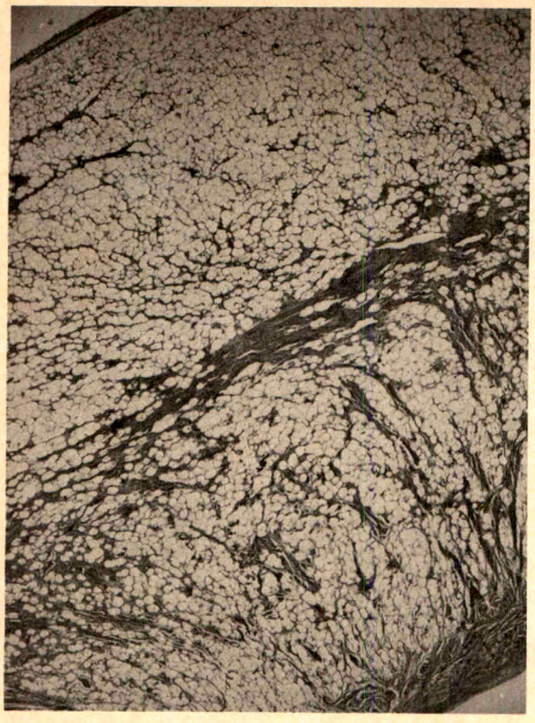

FIGURE 4. Histologic section of the valve tumor showing the mature fat cells. (Masson's trichrome stain; magnification ×25, reduced 13%.)

ical lobulated sessile yellow mass, 23 × 22 × 14 mm. The chordae tendineae of this cusp were thickened and emerged from another yellow 20 × 12 × 8 mm mass that had largely replaced the posterior papillary muscle (Fig. 3). The anterior cusp was normal. The mitral valve and the papillary muscles were excised and replaced by a 31 mm Björk-Shiley prosthesis. The postoperative course was uneventful. Histologic examination of sections of the valve and the papillary muscle tumors showed simple pure lipomas composed of mature fat cells (Fig. 4).

Valve lipomas are exceedingly rare. Two cases of lipoma involved the septal leaflet of the tricuspid valve.[1,2] Only 1 case of fibrolipoma of the mitral valve has been reported.[3] The present case is the first "pure lipoma" of the mitral valve to be reported. The M-mode echocardiogram disclosed the tumor in the posterior mitral leaflet but failed to identify the tumor in the posterior papillary muscle. Two-dimensional echocardiography showed both masses and provided better appreciation of their size, shape, location, and mobility.

Massive Right Ventricular Outflow Tract Aneurysm After Ventriculotomy for Subvalvular Pulmonic Stenosis Associated With Peripheral Pulmonary Arterial Stenoses

Jeffrey E. Saffitz, MD, PhD*
Charles L. McIntosh, MD, PhD
William C. Roberts, MD

Aneurysms that develop at sites of cardiac ventriculotomy incisions are recognized but infrequent consequences of such procedures.[1] Their development appears to be dependent on 2 major factors: (1) the peak systolic pressure within the ventricle after the incision, and (2) the length of the incision. The incidence of postventriculotomy aneurysm is far greater in the left ventricle than in the right because of the differences in peak pressures in each chamber. Herein, we describe a patient with *both* subvalvular pulmonic stenosis and peripheral pulmonary arterial stenoses in whom a massive right ventricular (RV) outflow tract aneurysm developed after operative relief of the subvalvular obstruction.

A 30-year-old woman (CC #05-28-81) had a precordial murmur at birth and cyanosis and clubbing of the digits by age 7 years. Results of 4 cardiac catheterization studies, summarized in Table I, confirmed the presence of subpulmonic obstruction, peripheral pulmonary arterial stenoses,

From the Pathology and Surgery Branches, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland.

Manuscript received and accepted January 4, 1983.

* On leave from the Department of Pathology, Washington University, St. Louis, Missouri.

TABLE I Hemodynamic Data

	Age (yr)			
Pressures (mm Hg)	8	15	Intra-operative	(6 mo PO) 16
Pulmonary artery (s/d)	100/	75/5	115/20	120/60
Right ventricle (s/d)	175/	180/7	120/20	120/16
RV inflow-outflow peak systolic gradient	75	105	5	0
Systemic artery (s/d)	. . .	110/60	120/60	120/70

PO = postoperative; s/d = peak systole/end-diastole.

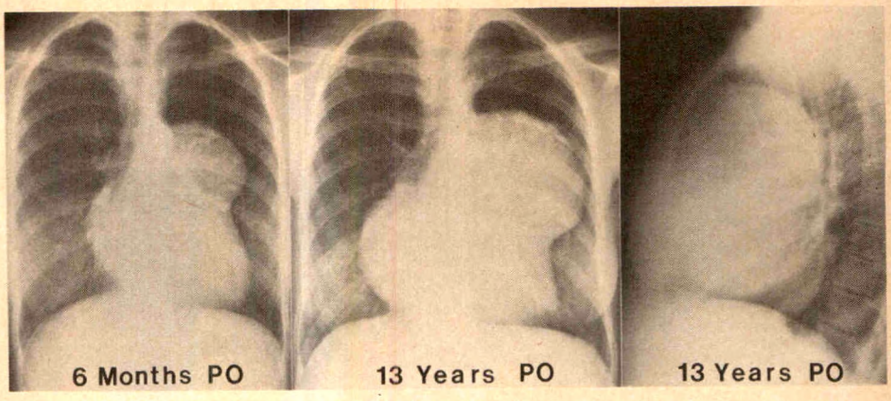

FIGURE 1. Radiographs of the chest 6 months and 13 years after operation, illustrating the development of the RV outflow tract aneurysm. A thin rim of calcium lines the wall of the aneurysm. PO = postoperative.

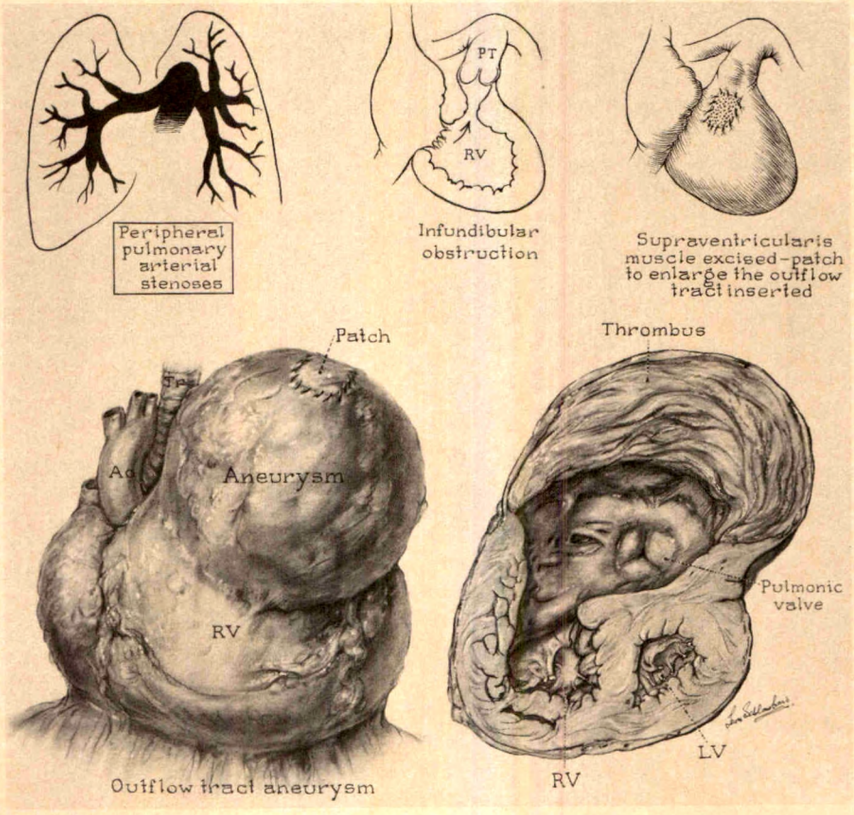

FIGURE 2. Diagrams illustrating various components of peripheral pulmonary arterial stenoses and RV infundibular obstruction, and the consequences of the right ventriculotomy. Ao = aorta; LV = left ventricle; PT = pulmonary trunk; RV = right ventricle.

and a right-to-left shunt through a patent foramen ovale. Syncope occurred at age 12 years, and by age 15 had become frequent and severe. The subpulmonic stenosis was operatively relieved at age 15 years by excision of portions of crista supraventricularis myocardium. A Teflon® fabric patch was used to enlarge the RV outflow tract. The patent foramen ovale was sutured closed.

Six months after operation, a pulsatile mass was present at the upper left sternal border of the heart (Fig. 1). During the next 13 years, the patient had no physical limitations and received no medications (functionally class I). She died suddenly at age 30 years after a febrile illness with hemoptysis.

At necropsy, the heart with the aneurysm weighed 830 g (Fig. 2 and 3). The RV outflow incisional aneurysm was partially filled with laminated thrombus and lined by focally calcified fibrous tissue. The aneurysm partially compressed the pulmonary trunk, left atrium, and left anterior descending coronary artery.

RV aneurysms of the magnitude described in this patient, to our knowledge, have not been described previously after right ventriculotomy. In this case, inoperable peripheral

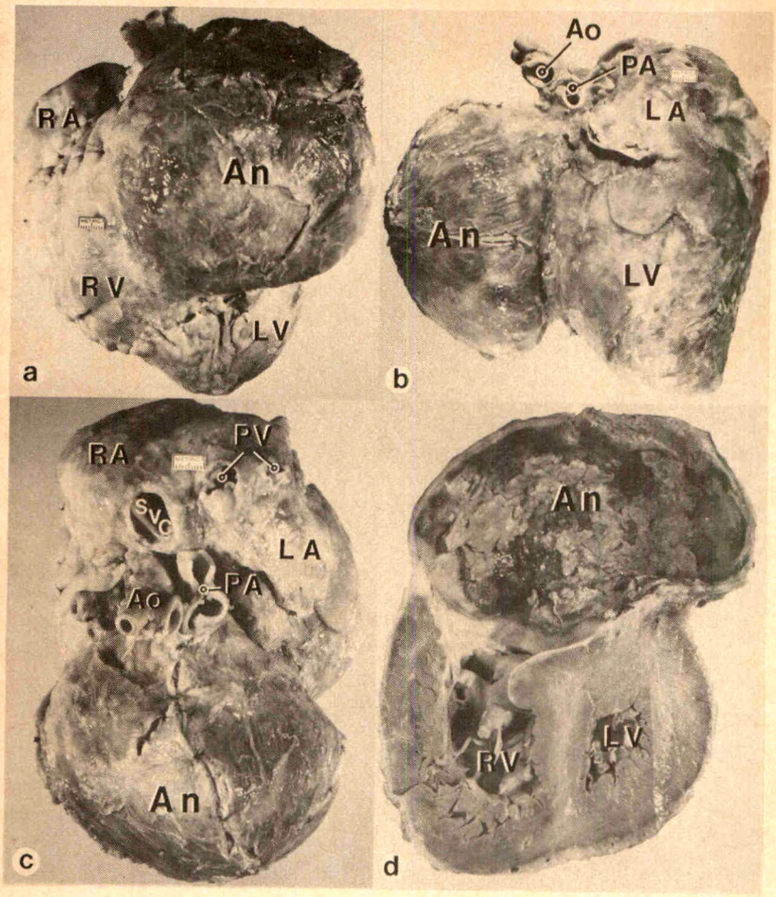

FIGURE 3. Photographs of the heart at necropsy including views of the anterior (**a**), left lateral (**b**), basal (**c**), and transverse cut (**d**) surfaces. The transverse cut illustrates the massive size of the aneurysm (thrombus removed) and the marked RV hypertropy. An = aneurysm; Ao = aorta; LA = left atrium; LV = left ventricle; PA = pulmonary artery; PV = pulmonary veins; RA = right atrium; SVC = superior vena cava. (Photographs by M. M. M. Moore.)

pulmonary arterial stenoses caused persistent, severe elevation of the RV systolic pressure, which in turn caused massive aneurysmal dilatation of the surgically incised RV outflow tract.

Progressive Pulmonary Arterial Stenosis

George S. Papadopoulos, MD
Gordon M. Folger, Jr., MD

Pulmonary arterial stenoses (PAS) are generally considered stable or nonprogressive malformations conforming to 1 of several anatomic configurations.[1] Documentation of progression in stenosis both anatomically and hemodynamically[2–5] has been rare, but such was the case in a patient we studied.

From the Clinic for Children with Cardiovascular Diseases, Department of Pediatrics, Henry Ford Hospital, Detroit, Michigan. Manuscript received November 19, 1982; revised manuscript received December 27, 1982, accepted January 4, 1983.

TABLE I Comparative Hemodynamic Data

Site	4.5 Months Pressure (mm Hg)	4.5 Months Oxygen Saturation (%)	45 Months Pressure (mm Hg)	45 Months Oxygen Saturation (%)
RA	m 1	65	m 5	44
RV	45/3	63	128/8	46
PT	42/5 (m 22)	60	126/62 (m 72)	44
LPA	20/0 (m 15)	...	...	...
RPA	23/10 (m 1)	61	...	...
LA	m 1	85	m 3	70
LV	...	...	112/10	79

LA = left atrium; LPA = left pulmonary artery; LV = left ventricle; m = mean; PT = pulmonary trunk; RA = right atrium; RPA = right pulmonary artery; RV = right ventricle.

A 45 month-old girl was obtunded, retarded, and in severe right-sided heart failure when first seen. Multiple congenital anomalies including PAS had been diagnosed at age 4.5 months (Table I, Fig. 1). The height and weight were average

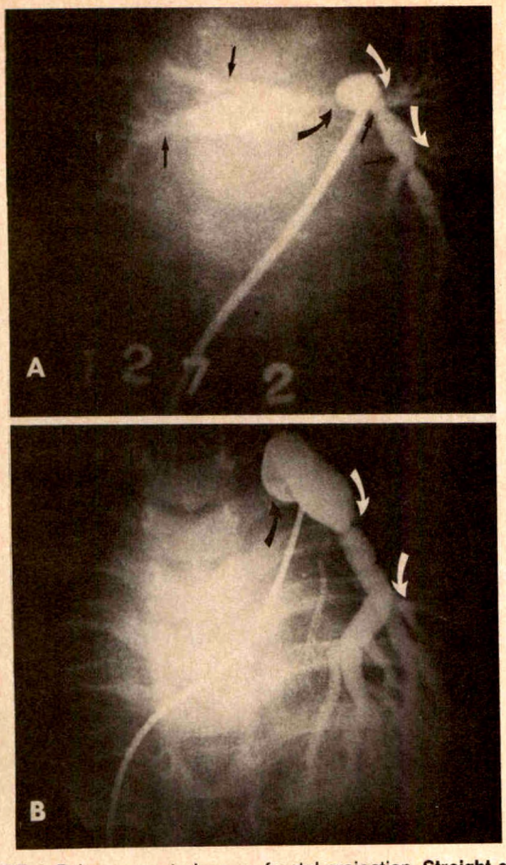

FIGURE 1. Pulmonary arteriogram, frontal projection. **Straight arrows** indicate major areas of stenosis; **curved arrows** denote those areas which may be identified as having progressed to total occlusion. **A,** 4.5 months of age; **B,** 45 months of age. Note the enlargement of vessels to the left lower lobe, resulting from near-total pulmonary blood flow to this area.

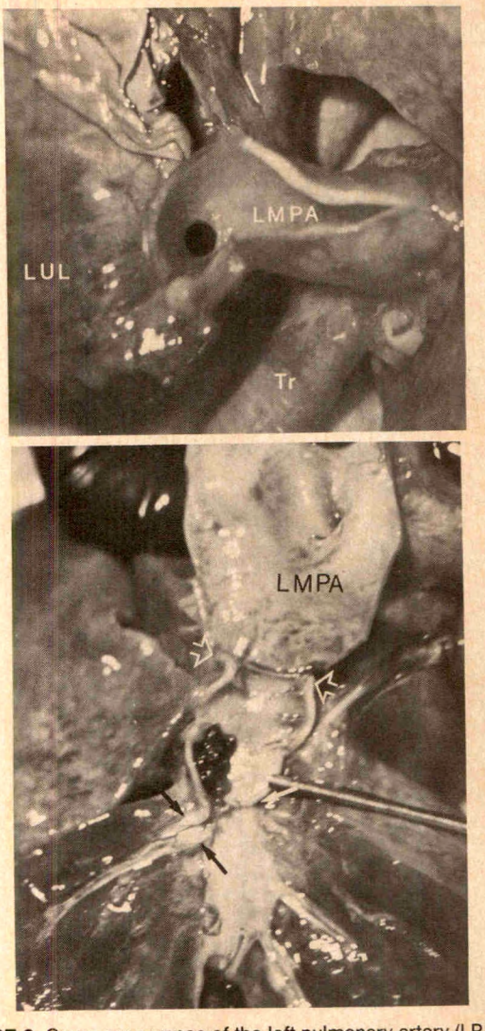

FIGURE 2. Gross appearance of the left pulmonary artery (LPA). **Top panel,** close-up of the left main pulmonary artery (LMPA) exposing first stenotic area just proximal to the left upper lobe (LUL) branch. The lesion is concentric, and its edges are smooth. **Bottom panel,** view of the entire left pulmonary artery. **Open arrows** indicate stenosis seen in the top panel; **solid arrows** indicate stenoses seen angiographically (see Fig. 1). Tr = trachea.

for a child of 12 months of age. She had coarse facial features, posteriorly positioned low-set ears, a bifid uvula, and hydrocephalus (treated earlier by ventriculoperitoneal shunt). Deep cyanosis and the murmurs of tricuspid and pulmonic valvular regurgitation were present.

Repeat cardiac catheterization (Table I, Fig. 1) disclosed more severe PAS with suprasystemic main pulmonary arterial systolic pressure and a large right-to-left shunt through the atrial septum. She died 8 days after this study.

At necropsy, multiple "shelf-like" projections involved both the major and the peripheral pulmonary arteries (Fig. 2). The pulmonary trunk was spared. Microscopically, the obstructing lesions were composed of discrete excrescences of hypertrophic media having an otherwise normal appearance.

PAS of a degree sufficient to produce systemic or suprasystemic systolic right ventricular and pulmonary arterial pressures is well recognized.[6] Progression of PAS, to the contrary, has been reported in only 4 patients[2–5] in whom the condition was isolated. Our patient is the only individual with hemodynamic documentation of progression substantiated by serial angiographic evaluation and confirmed by necropsy.

The cause of the progression in severity was not determined. It was clear, however, that thromboembolism was not a contributing factor. The relation of this child's obvious multiple anomalies with the PAS suggests a singular origin for the malformations.

HOLTER VERSUS ELECTROPHYSIOLOGIC STUDIES IN THE MANAGEMENT OF MALIGNANT VENTRICULAR ARRHYTHMIAS

We read with gratitude the report of the experience of Graboys et al[1] in treating patients with malignant ventricular arrhythmias with antiarrhythmic drugs. These observations by a very experienced group are an important landmark in the search for methods for managing patients at high risk of death due to arrhythmias. We will comment briefly on the study in general and then argue with 2 points made by these investigators: (1) the method is simple, inexpensive, and therefore easy to apply; and (2) the method is preferable to electrophysiologic guided treatment.

Graboys et al conducted an observational study, not an experimental one. Their patients are highly selected so that their sample is subject to biases that hamper inferences and extrapolation of the results to other institutions and patient groups. The 2 subgroups that are compared, that is, those that respond to antiarrhythmic treatment and those that do not, are not well characterized at baseline with respect to presence and extent of coronary artery lesions or left ventricular dysfunction. The authors state that left ventricular function is not different in the treatment responders and nonresponders. However, the left ventricular dysfunction data are weak on 3 counts: (1) only 64% of the patients had any measure of left ventricular dysfunction; (2) 3 different methods were used to estimate the ejection fraction (echocardiography in 37% of the cases); and (3) the ejection fraction cutpoint used for left ventricular dysfunction (that is, 50%) was too high. Because of these problems the misclassification rate is likely to be high. The assessment of left ventricular dysfunction would have been better if all patients had had radionuclide ventriculography to estimate the ejection fraction and if a cutpoint of 30 or 35% had been used. Because of these problems in evaluating left ventricular dysfunction, differences at baseline could account for differences in outcome. Also, there was no randomization or systematic assignment to alternative treatment regimens. Very little information was given on drug sequencing and selection. What were the 3 or 4 most common drug combinations and what was the prevalence of digitalis use? Which regimens most frequently caused adverse effects during a year of follow-up? How were changes to new treatments managed? We do not learn much from this report about the comparative worth of treatments. Nevertheless, these flaws are tolerable considering the state of knowledge in this field and the hypothesis that the authors wanted to test, although we will have to await confirmatory observational and, better yet, experimental studies before we can generalize the result.

Graboys et al assert the Holter- and exercise-guided antiarrhythmic treatment is more practicable, cost-effective, and widely applicable than electrophysiologic guided treatment. Certainly, some highly organized program is warranted for patients with life-threatening ventricular arrhythmias, and the 2 most appealing candidates are Holter-guided and electrophysiologic-guided treatment. However, we believe their assertion is debatable. Therefore, we will compare these 2 methods briefly in terms of patient selection, endpoints, ease of antiarrhythmic drug selection, safety assessment, compliance evaluation, complexity, and cost.

Patient selection: Both methods are inconvenient and costly so that only patients who have significant symptoms or risk of mortality or morbidity risk should be selected. A Holter- or telemetry-guided approach is clearly better for patients with incessant ventricular tachycardia. The electrophysiologic method is preferable for patients who have infrequent episodes of ventricular tachycardia or ventricular fibrillation or those with a very low frequency of ventricular premature depolarizations (VPD). For many patients either method can be used.

Endpoints: The Holter-exercise method as advocated by Graboys et al uses total abolition of Lown grade 4B or 5 arrhythmias as the criterion for successful drug treatment. This is not a simple objective. Graboys et al have painstakingly developed a method for detecting repetitive and R-on-T VPD in 24-hour electrocardiographic (ECG) recordings. However, routine clinical analysis of 24-hour ECG recordings misses many of the episodes of ventricular tachycardia,[2] and even research arrhythmia detection systems have difficulty in reliably detecting the R-on-T phenomenon. There is little risk in Lown grade 5 for those patients who do not have repetitive VPD.[3] These problems do not adversely affect the results reported by Graboys et al, but they do limit very significantly the widespread application of the method. In electrophysiologically guided treatment, success is defined as abolition of inducible ventricular tachycardia or fibrillation. Nonsustained ventricular tachycardia less than 6 complexes in duration also is considered a success. With either method the endpoint is relatively crisp, but the endpoint is more difficult to determine by Holter techniques.

Ease of drug selection: Graboys et al test for efficacy in 2 phases: (1) acute drug testing, and (2) short duration maintenance. Acute drug testing requires 6 to 7 hours of observation and trendscription along with many determinations of serum drug concentration. An average of 6 acute drug tests are required per patient. Phase 2 testing requires 48 to 96 hours for each drug tested (many drugs can only be tested in phase 2) and multiple Holter ECG recordings and exercise tests. Finally, 2 or more drugs that were effective singly are given together for long-term treatment. Multiple drug use is based on the failsafe concept. However, adverse drug interactions also can result from this practice. Electrophysiologic testing requires a day between drug trials to permit the body to eliminate antiarrhythmic drugs. Each test session takes 2 to 4 hours because dose ranging with repeated stimulation is usually performed. Usually, 2 effective drugs are sought but only 1 is used for long-term treatment. The process of drug selection is somewhat simpler to interpret with the electrophysiologic method. Both methods have significant, but poorly defined, reliability problems, that is, between-day variance. In theory, drugs may prevent ventricular tachycardia by reducing the VPD which trigger tachyarrhythmias or by increasing the tachycardia or fibrillation threshold so that VPD can no longer initiate malignant arrhythmias, or by both actions. The Holter approach may show a marked reduction in VPD frequency when electrophysiologic studies show the ventricle to be still inducible. Conversely, inducibility by programmed ventricular stimulation may be abolished even though VPD do not reach the criteria for successful treatment used by Graboys et al.

Safety assessment: Holter-guided therapy may identify patients whose ventricular arrhythmias are worsened by antiarrhythmic drug treatment.[4] However, recognition is hampered by between-day variability in arrhythmia rates. Holter recordings also are excellent for detecting adverse drug effects on the sinus node, atrioventricular node, and His-Purkinje system. Electrophysiologic studies are excellent for detecting aggravation of the target arrhythmia. Also, the electrophysiologic method can detect the patient whose ventricular premature depolarizations and nonsustained ventricular tachycardia improve markedly while his sustained ventricular tachycardia becomes easier to induce or more life-threatening; this situation cannot be detected by the Holter method. The electrophysiologic method is probably more sensitive in detecting adverse drug effects on cardiac automaticity and conduction. Given the high rate of adverse effects with currently available antiarrhythmic drugs, both methods should be used in many patients with life-threatening ventricular arrhythmias.

Compliance evaluation: As a rule, patients with life-threatening arrhythmias are very compliant with treatment recommendations. Holter recordings can be used to assess patient compliance and arrhythmia stability during follow-up. Electrophysiologic studies are more cumbersome to use in this way. Usually, electrophysiologic studies are not repeated during follow-up unless symptoms or arrhythmias recur. For both methods, serum drug concentrations are conve-

* Letters (from the United States) concerning a particular article in the *Journal* must be received within 2 months of the article's publication, and should be limited (with rare exceptions) to 2 double-spaced typewritten pages. Two copies must be submitted.

nient and useful adjuncts for evaluating compliance.[5]

Complexity: Both Holter-exercise and electrophysiologic approaches are reasonably complex; their degree of complexity is quite similar. Both methods require well-organized, often-used programs for efficiency and effectiveness. It is unreasonable to assume that physicians who only occasionally see patients with malignant arrhythmias can effectively use either method without assistance.

Cost: There is no significant difference in cost between the Holter-exercise program recommended by Graboys et al and electrophysiologic approaches. The cost of the large number of 24-hour ECG recordings and exercise tests used by Graboys et al[1] often would exceed the cost of serial electrophysiologic testing plus a few adjunctive Holter ECG recordings. Both techniques make liberal use of serum drug concentration measurements. The hospital stay is approximately equal for the 2 methods, with the average stay being somewhat shorter for the electrophysiologic method. The hospital stay can be longer with the electrophysiologic method when all drugs fail. The longer stay can be attributed to the additional time required for arrhythmia surgery or implantation of an automatic defibrillator. However, these avenues of treatment also are appropriate for drug failures in the Holter-exercise approach.

Summary: Empirical management of patients with malignant ventricular arrhythmias is unsatisfactory. Therapy must achieve endpoints that predict improved likelihood of survival. Both the Holter-exercise approach and the electrophysiologic approach have been proposed for this purpose, but there have been no controlled comparisons of these 2 methods. Graboys et al cite some of the several studies that demonstrate the effectiveness of the electrophysiologic approach. Now that the Holter-exercise method has been reported effective by Graboys et al, we must compare this alternative with the better-established electrophysiologic method with respect to efficacy, efficiency, and safety. There appears to be no significant difference in the cost of the 2 approaches. Both methods are complex enough to warrant the recommendation that they be employed by experienced groups. We must await future comparative studies, hopefully experimental ones, to define any overall preference between these 2 approaches or to combine elements of each into a single program.

REPLY: We welcome Bigger and Reiffel's carefully honed argument questioning some of the conclusions of our study. Their thoughtful analysis demands a detailed response, especially since the issues raised are of pressing contemporary relevance. But before joining the dialogue, it needs to be stressed that the points they dispute are quite peripheral to the central motif of our presentation.

Our study reported 2 essential findings: (1) that patients having sustained malignant ventricular arrhythmias can be protected against recurrence by tailoring antiarrhythmic drug therapy to the individual patient, and (2) that the selection and dosing with an appropriate drug can be guided by reduction in prevalence of ventricular premature beats and more specifically by elimination of their advanced grades. To achieve this therapeutic objective we devised a number of new methods. Bigger and Reiffel only tangentally deal with the essential objectives and the underlying hypothesis.

Bigger and Reiffel preface their main objections with a number of diverse criticisms, and these need to be disposed of first. They complain that ours was an observational, not an experimental study. They thereby posit spurious levels of revealed truth. A sound observation is certainly to be preferred to a shoddy experiment. Even beyond the casuistry, how is one to conduct an experimental study in patients who have identified themselves as being at imminent risk for sudden cardiac death? Does not protection of survival take precedence over nearly all other considerations?

Bigger and Reiffel fault our study for dealing with highly selected patients. Indeed, this is the case of any hospital-based study with its complex referral pattern. This truism in no way vitiates the findings if the sample population is adequately defined. They complain of the incompleteness of hemodynamic data. We agree. Nevertheless, among 44 patients who had substantiated hemodynamic impairment demonstrating markedly reduced ejection fractions, control of ectopic activity continued as a critical determinant of survival.

Bigger and Reiffel furthermore demand randomization and systematic assignment to alternative treatment regimens, details about drug sequencing and selection, the use of drug combinations, the employment of digitalis, data on long-range adverse drug effects, changes to new treatment schedules, and so on. In effect, they throw the book at us for not having written a different and more encyclopedic article. Some of these questions are answered in other recent reports.[1–5]

But the very questions they do pose indicate a failure to grasp our essential thesis: that it is not a particular antiarrhythmic agent which is decisive; rather, any drug which reduces ventricular premature beats of advanced grade will improve survival. We are delighted that "these flaws are tolerable" and can turn now to the central issue.

Bigger and Reiffel question primary reliance on Holter-exercise studies for drug selection to treat malignant ventricular arrhythmias. They prefer electrophysiologic testing. One searches in vain in their long letter for evidence to buttress this viewpoint. Their final words indicate a different conclusion. They suggest the need for comparative studies of the 2 approaches to define "overall preferences." As no such data exist, why prefer one method to another until the evidence has been marshalled? Hence, the collateral points raised by Bigger and Reiffel are of some consequence and deserve systematic examination.

Patient selection: Bigger and Reiffel acknowledge that patients with frequent paroxysms of ventricular tachycardia do not require electrophysiologic studies, presumably because monitoring is less costly and traumatic than an invasive approach. Would it not be sensible to extend the same logic to those with frequent and reproducible ventricular premature beats? We would readily agree that at the other extreme of the spectrum, those who have had potentially lethal ventricular arrhythmias but are free of reproducible ventricular ectopic activity require electrophysiologic studies. Among 260 patients with recurrent malignant ventricular arrhythmias, we have had to resort to electrophysiologic testing in 52 (20%) because of a paucity of ectopic activity.

Endpoints: The impression conveyed is that the electrophysiologic method is standardized, reproducible, and has a well-defined endpoint. As far as we know no consensus exists as to the number of pulses, the current level, the pacing rate, the precise locus for stimulation, the need for multiple sites, or what constitutes sustained ventricular tachycardia. We would welcome reference to rigorous studies defining specificity and sensitivity of electrophysiologic testing with a standardized method and a predetermined endpoint. At the 55th Scientific Session of the American Heart Association, the presentation dealing with electrophysiologic testing sounded more like that at a Tower of Babel than like scientific reports of a method with a "crisp" endpoint.

A basic problem with electrophysiologic testing that precludes a precise endpoint is that the elicited response represents part of a biologic continuum relating largely to properties of the test stimulus. It is difficult to define rigorously a normal or abnormal response when ventricular tachycardia and fibrillation can be provoked in the normal heart as a function of current strength, the pacing rate, and the sequencing of stimuli. The spectrum of response among those with arrhythmia and diverse forms of heart disease is unknown. Therefore to adduce exactitude to this approach at best is premature and most probably will prove elusive.

Ease of drug selection: In choosing a drug one must be attuned to its pharmacokinetic and pharmacodynamic properties. While drug efficacy may be judged by an electrode catheter, this affords information only for the particular avenue of administration for 1 point in time, and for a single employed dose level. Furthermore, it does not predict patient tolerance during chronic drug administration. Our Phase 1 and Phase 2 provide the clinician

with more comprehensive information on drug response and tolerance over 24 hours and permit greater flexibility than is to be gained during a brief electrophysiologic study. In addition, with some drugs studied electrophysiologically there is disparity between tests results and clinical outcome. This is true with amiodarone and perhaps also with encainide. We have not encountered such a phenomenon with our method.

Safety assessment: Bigger and Reiffel disregard an important element in our methodology: acute drug testing (Phase 1). This phase facilitates recognition of adverse drug effects without the need for Holter monitoring and can be readily performed at the bedside.[6] The follow-through with Phase 2 study enhances this type of information, precluding frequent and costly rehospitalizations for adverse drug reactions. Ascribing special virtue to electrophysiologic testing for recognizing arrhythmia aggravation is astonishing when one considers the paucity of meaningful data.

Compliance evaluation: Bigger and Reiffel admit the superiority of the Holter-exercise method in follow-up, but this admission underscores the illogic of their position. In the real world, outside academia, life does not proceed on a predictable and smooth trajectory. There arise needs for other medications, the patient confronts bereavement and diverse physical and emotional stresses, infection and other illness may occur, and a host of other events can modify the mode of action of the administered antiarrhythmic. How is the physician to judge whether protection is still being afforded? Suppose the antiarrhythmic agent provokes symptoms and the dose needs adjustment: how is one to assess continued drug efficacy? In dealing with a potentially lethal arrhythmia, is it permissible to indulge the luxury of an educated guess? Does not the electrophysiologic approach encourage frequent and costly rehospitalization to assure the physician, under the aforementioned circumstances, that drug effectiveness is maintained?

But here the cross-stitch of logic is completely tattered. Bigger and Reiffel counsel Holter monitoring. Is life less valued for the outpatient to justify resorting to an inferior method of evaluation? They do not delineate the endpoint to be sought with Holter monitoring. Is one to be attentive to mere presence of ectopic beats, to their frequency, to the occurrence of advanced grades, or to only paroxysms of tachycardia? And once the selected endpoint is to be exposed, what may be inferred as to the efficacy of the antiarrhythmic drug being employed? Without prior experience with Holter or exercise testing during initial drug use, how is one to draw sensible therapeutic inferences? If treatment modification is to be affected by Holter-exercise findings during follow-up, one would surmise that it is equally appropriate to employ these methods during initial drug selection. Or are we to conclude that in the real world Bigger and Reiffel would resort to repeated costly hospitalizations for executing electrophysiologic studies?

Complexity: The argument relating to complexity batters at an open door. We have not suggested that treating patients with life-threatening arrhythmias is a simple endeavor. It requires a careful program as well as much expertise. We believe the issue is of a different sort. Patients afflicted with recurring malignant ventricular arrhythmias constitute a miniscule subset of those threatened with sudden death. While the electrophysiologist is concerned with the former, the practicing cardiologist and internist confront the latter. At present the most practicable method for identifying the coronary heart disease patient at risk for sudden death is by exposing the presence of advanced grades of ventricular premature beats by means of Holter-exercise methods. The system of treatment which we have evolved is primarily intended for application by physicians encountering patients at risk for sudden death. Behind the facade of words there may be a subtle struggle over turf.

Cost: This last point raised by Bigger and Reiffel is especially astonishing since the cost of an electrophysiologic study is far greater than that of Holter and exercise tests combined. Ross et al[7] in 1980 estimated electrophysiologic testing to cost $800. But the approach of Bigger and Reiffel requires the employment of both methods: "Given the high rate of adverse reactions with currently available antiarrhythmic drugs, both methods should be used in many patients with life-threatening ventricular arrhythmias." They may find an escape hatch with the word "many," but if the dual approach is optimal for some such cases, why should it not be employed in all? Certainly it is sheer casuistry to imply that the use of 2 methods may be less expensive than either.

An aspect completely ignored by Bigger and Reiffel relates to the human cost. Where in all this discussion is the patient—the invaded, frightened, psychologically stressed patient? In the series of Mason and Winkle,[8] 52% of patients studied electrophysiologically required emergency cardioversion because of accelerating rate or hemodynamic instability. Speilman et al[9] encountered ventricular fibrillation in 10 (15%) of 68 patients who were being subjected to extrastimuli testing for recurrent ventricular tachyarrhythmias. Horowitz et al[10] reported the need for emergency cardioversion in 21%. These are profoundly traumatic experiences not easily forgotten, which in some patients become the psychologic trigger for the very arrhythmia we aim to prevent. There are, of course, other complications such as deep venous thrombosis and pulmonary emboli (4.4%), local or systemic infections (2.9%), and pneumothorax (2.4%).[11] While there are no cardiac enzyme changes induced by electrophysiologic testing, terror in the human heart is not readily assessed by such biochemical means.

In summary: The ventricular premature beat provides a suitable target for antiarrhythmic drug selection, dosing, and adjustment in hospital and in later follow-up. The method is especially powerful when both Holter monitoring and exercise testing are employed to assess drug response. Abolition of advanced grades of ventricular premature beats affords protection in those at high risk for sudden death. Our initial report dealing with 123 patients has now been extended to more than 300 patients, and the results continue as reported. In a small subset of 20%, electrophysiologic testing is mandated by the paucity of ectopic activity. We concur with Bigger and Reiffel's last sentence suggesting the need for comparative studies. It is our conviction, though, that the specific presentation of a clinical problem must guide in the choice of a particular methodology.

HYPERPROLACTINEMIA-GALACTORRHEA INDUCED BY VERAPAMIL

In 1981 a single case of verapamil-induced hyperprolactinemia and galactorrhea was reported.[1] As part of our participation in the clinical evaluation of verapamil by Knoll Pharmaceutical, we studied the drug in 7 women and 1 man. Clinical galactorrhea developed in 3 of the 7 women and hyperprolactinemia or galactorrhea, or both, developed in 6. The serum level in the 1 man was normal. The appearance of galactorrhea did not correlate with the degree of elevation of serum prolactin. No woman had amenorrhea or abnormal thyroid studies or was taking medications known to induce hyperprolactinemia or galactorrhea such as methyldopa, oral contraceptives, reserpine, or phenothiazines. One patient with galactorrhea was taken off verapamil, and the galactorrhea completely disappeared. She was subsequently placed on nifedipine with no resumption of galactorrhea. In the absence of hypothyroidism or elevated thyrotropin-releasing hormone (TRH), the most logical mechanism for verapamil hyperprolactinemia would be interference with the release or synthesis of prolactin inhibitory factor in the hypothalamus.[2,3]

Galactorrhea, usually with amenorrhea, may occur spontaneously (Argonz-del-Castillo syndrome) in the postpartum state (Chiari-Fromel syndrome) or may be asso-

ciated with pituitary tumors (Forbes Albright syndrome).[2,4]

This study confirms the development of hyperprolactinemia in 6 and galactorrhea in 3 women initially treated with verapamil. In none did amenorrhea develop, which may be a diagnostic point in support of verapamil hyperprolactinemia-galactorrhea as opposed to other causes of this syndrome.

This study confirms that hyperprolactinemia and galactorrhea are frequently associated with verapamil therapy. Because of the excellent response to verapamil, it was medically inadvisable to withdraw therapy to evaluate prolactin levels off medication. The true frequency of hyperprolactinemia and galactorrhea associated with verapamil therapy is unknown, but on the basis of our study it occurs in a significant number of patients. With the increasing number of women being placed on verapamil therapy for recurrent paroxysmal supraventricular tachycardia, the association of hyperprolactinemia and galactorrhea with this therapy should be recognized.

SUDDEN DEATH IN A MARATHON RUNNER WITH ORIGIN OF THE RIGHT CORONARY ARTERY FROM THE LEFT SINUS OF VALSALVA

We read with interest the article by Roberts et al[1] in your March 1982 issue which dealt with the origin of the right coronary artery from the left sinus of Valsalva and its functional consequences. We recently were involved in a case of sudden death in a 26-year-old marathon runner who was training for the Iron Man Triathalon in Hawaii. He had been swimming, exercising, weight lifting, and marathon running and collapsed just past the finish line of a 13.5 mile marathon. The anatomic findings were identical to those described by Roberts et al and included a slit-like right coronary ostium and a flattened right coronary artery which coursed between the aorta and pulmonary artery. The anomalous right coronary artery supplied both the atrioventricular and sinoatrial nodes and was the dominant coronary artery. All 4 cardiac chambers were hypertrophic and the heart weighed 420 g. The decedent had had at least 2 episodes of shortness of breath after long runs, which was atypical of his normal postmarathon experience, but he attributed the symptoms to inadequate fluid intake.

The details of this case were reported in the March 1983 issue of *The American Journal of Forensic Medicine and Pathology*. The case further supports the opinion of Roberts et al that anomalous origin of the right coronary artery from the left sinus of Valsalva can no longer be considered a minor congenital anomaly of no clinical significance, as it may be associated with sudden death in young and otherwise healthy persons.

PROLONGATION OF Q-T INTERVAL AND INCREASED AMPLITUDE OF THE T WAVE AFTER TERMINATION OF VENTRICULAR TACHYCARDIA

Soffer et al[1] described (in their Figure 2) a patient with ventricular tachycardia (VT) and noted prolongation of the Q-T interval following the first beat after cessation of VT. The T wave of this beat was taller than that of the subsequent sinus beats. The following description pertains to a 1-day-old male infant in whom short runs of VT developed at birth. He was asymptomatic, without precordial murmurs, and had a normal-sized heart and normal pulmonary vascularity. Serum electrolytes, including calcium and magnesium, were normal. The surface electrocardiogram showed an axis of +120° with no evidence of atrial or ventricular hypertrophy. The Q-T interval was 0.40 second (Q-Tc = 0.54 second) during sinus rhythm, and the T wave was flat in all 12 leads. The Q-T interval of the first beat after termination of VT (Fig. 1) was still 0.40 second (Q-Tc = 0.56 second), but the T wave was taller than that of the subsequent sinus beats. The T wave of the last beat of the VT also was tall. These findings were consistently observed after termination of every short run of VT. The patient has been treated with propranolol for 1 year and the Q-T interval has normalized. Thus, a prolonged Q-T interval is associated with VT.

The finding of a tall T wave in the first beat after termination of VT as well as in the last beat of VT is unusual. Cohen et al,[2] by microelectrode technique, studied the action potential duration of the upper part of the ventricular septum and the epicardial surface of the apex of the left ventricle of sheep to clarify the genesis of the polarity of the T wave of the surface electrocardiogram. They found that the steady-state action potential duration of the apex of the left ventricle was shorter than that of the upper part of the septum. This difference would account for a positive T in the electrocardiogram. This phenomenon of a longer Q-T interval in the first beat after cessation of VT associated with increased amplitude of the T wave may

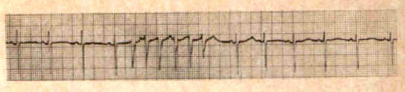

FIGURE 1. Electrocardiographic lead II reveals a tall T wave in the last beat of VT and in the first sinus beat after termination of the arrhythmia in my patient.

be secondary to differences in the action potential duration of different ventricular sites. These differences were probably markedly increased because in both patients VT ceased just before the described findings. These findings imply that the mechanism of VT in both patients was reentry. In the patient reported on by Soffer et al,[1] the Q-T interval and the amplitude of the T wave decreased once sinus rhythm was established. In my patient, the T wave flattened after resumption of sinus rhythm. These findings might be explained by more uniform depolarization of the ventricles during sinus rhythm.

Prolongation of the Q-T interval in the first sinus beat after cessation of VT and the tall T wave observed in the last beat of VT and the first sinus beat after termination of VT may give clues about the mechanism of the dysrhythmia.

PTCA: NEED FOR PROSPECTIVE RANDOMIZED CONTROLLED TRIALS

The report from the National Heart, Lung, and Blood Institute (NHLBI) registry of percutaneous transluminal coronary angioplasty (PTCA) is an impressive document, if only for its 17 authors.[1] As an invited commentator at the NHLBI Conference in June 1981 from which this work emanates, I was duly impressed by the attractive—even seductive—results. Yet, it is distressing that the distinguished authors do not at least mention the possibility of, let alone the necessity for, appropriately designed prospective randomized controlled trials of PTCA. I raised that issue at the Conference and it was fairly intensely discussed—though, to be sure, probably not agreed to by most of those actually doing the procedure (no votes were taken). The issue is even more sharply drawn when we read the words of Dr. Gruentzig, an author of this report and the brilliant pioneer of the method: "However, the results in pa-

tients with single-vessel disease are sufficiently good to make the procedure acceptable for prospective *randomized trials. Such trials are clearly needed* if we are to evaluate the efficacy of this new technique as compared with current medical and surgical treatments"[2] (emphasis mine). When this unambiguous statement was cited on a slide at the Conference, the reply (not only from Dr. Gruentzig) was that patients were being referred specifically for the procedure and it could not be denied to them. (One wonders whether such unambiguous statements—and there are many[3]—appended to papers in prestigious journals are more of a victory for "revision accepted" than "principle accepted").

The foregoing in no way denigrates the careful and otherwise scientifically sound work that has been done by Gruentzig, Myler, and the many other excellent cardiologists who have proceeded with PTCA step by step and deliberately, rather than with the unseemly haste that characterizes too many innovators. Yet it is these outstanding workers, with the highest prestige in the field, who are best qualified to perform appropriately designed trials, so that we will have acceptable denominators for the numerators that they have generated with such care—not to mention the expected avalanche of numerators, now that the genie is well out of the bottle. I suspect that if most of us had a lesion amenable to PTCA we would prefer PTCA to bypass if we could be sure PTCA was better in the long run. (The authors have established its relative safety[1]). Until that is accomplished, PTCA remains a brilliant technical *tour de force* of great promise.

All therapeutic innovations are of uncertain value when we expose the first patient to them; we have hopes, but cannot then know the short-term, and especially the long-term, results. This mandates controlled clinical trials, scientifically and ethically, from the very first patient. "Learning curves" and adjustments in dosage and technique do not invalidate that concept, since with random allocation to innovation or standard treatment, it requires only *patience* on the part of the investigator. It would merely take twice as long as in an uncontrolled trial (including changes in method), since half the patients would be in the control group—the genuine denominators that should make the results unimpeachable. Thus, from Patient Number One on, all patients would get a 50-50 chance to receive best treatment, which ultimately becomes the new treatment or established treatment. This approach—mandatory with pills and injections—requires a little patience but, if successful, it should eliminate the necessity for letters like this one.

David H. Spodick, MD, DSc
Worcester, Massachusetts

1. **Kent KM, Bentivoglio LG, Block PC, et al.** Percutaneous transluminal coronary angioplasty: report from the registry of the NHLBI. Am J Cardiol 1982;49:2011–2020.
2. **Gruntzig AR, Senning A, Siegenthaler WE.** Nonoperative dilatation of coronary artery stenosis. N Engl J Med 1979;301:61–68.
3. **Spodick DH.** The randomized controlled clinical trial: scientific and ethical bases. Am J Med 1982;73:420–425.

REPLY: Spodick has again[1] correctly emphasized the value of randomized studies to elucidate therapeutic procedures. In answer to his former letter,[2] we tried to encourage others to help us to formulate a protocol for randomization because the call for randomization is easily made but difficult to follow, especially in centers in which patients are referred from other centers for this special procedure and not for randomization. And, as we pointed out, each referring center should therefore randomize its own cases before referral is made. In addition, one must create 3 groups of matched patients: medical, surgical, and angioplasty, if Spodick had such a study in mind. As we all know, crossovers in these 3 subsets are a burden and occur because these forms of therapy are intrinsically different. For instance, after coronary dilatation as well as after coronary bypass surgery, almost 50% of our patients remain on medical therapy, so it is difficult to cleanly separate the effects of revascularization and medical therapy.

The problem is therefore what to randomize the patients to besides PTCA. The vast majority of our patients have unsatisfactory control of symptoms despite medical therapy or very proximal LAD stenosis with a large mass of myocardium at risk. Even though our surgery is excellent at Emory University, it is still associated with a 0.4% mortality and a 4.4% incidence of Q-wave infarction in single-vessel disease.[3] For our entire series of over 1,100 cases (90% single-vessel disease), we have had 1 in-hospital death (0.1%) which was noncardiac and a 2.1% incidence of Q-wave infarction. For the last 300 cases we have had 2 Q-wave infarctions (0.7%). These results underline the report of the National Institutes of Health PTCA Registry[4] and establish the relative safety of the procedure. Faced with these results, we do not see the need for a randomization of this subset of patients, but it might be needed for other subsets, such as those with multivessel disease. In regard to the long-term benefits, prospective studies are underway to determine the patency of vessels after angioplasty. These results will be compared with the patency of bypass grafts already well known from published reports.

We do believe in the randomized trial for difficult and important medical questions. We are using this valuable instrument to explore the effects of various therapies on our primary and long-term results. In our hospital, randomized studies are currently underway to test the effect of exercise training and various drug regimens in the prevention of recurrent stenosis. We are testing by randomized studies the effect of streptokinase infusion for myocardial salvage in acute myocardial infarction.

Your patients deserve the best ECG analysis they can get.

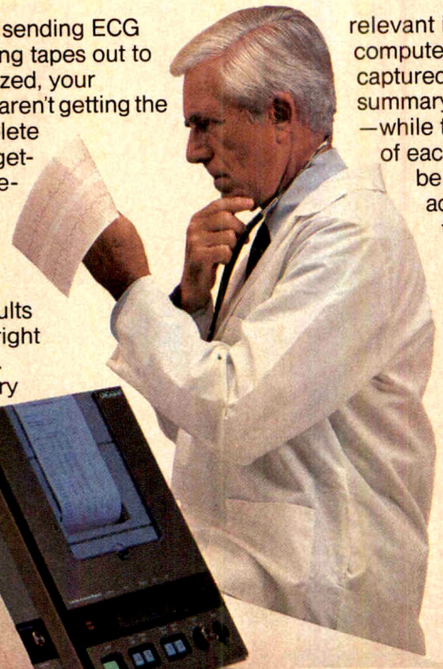
Yours. If you're sending ECG monitoring tapes out to be analyzed, your patients aren't getting the kind of analysis they can have complete confidence in: yours. And *you're* not getting results that are as complete, time-saving and technically sophisticated as possible.

But now you can, with the new, two-channel CircaMed with multi-dimensional analysis. It puts the results of real-time ambulatory monitoring right where they belong: in your practice.

With CircaMed, your patient's every heartbeat is analyzed, but only relevant information is recorded, under micro-computer control. Up to two days of patient data are captured on two multi-dimensional channels; a summary is then printed in your office within minutes —while the patient is still there. A strip chart record of each 10-second ECG measurement can also be quickly produced for further diagnostic accuracy. And because CircaMed is simple to use, a specially trained technician isn't required.

That means now neither you nor your patients have to worry about who's in charge of their ECG analysis: you are. You can both count on getting results quickly, economically and with complete confidence.

To find out how easy it is to bring ECG analysis into your practice, write us today for a brochure or demonstration: 777 Palomar Avenue, Sunnyvale, CA 94086. Or call: (800) 538-1772. In California (408) 738-8550.



CIRCADIAN

Leaders in real-time ECG analysis.

In the CCU, after conversion of VF...

Bretylol® (bretylium tosylate)

Follow-up therapy helps maintain stabilization

During the two or three days **after** conversion of ventricular fibrillation, the patient may still be electrically unstable. During this critical high risk period, **another** episode of VF may occur, completely unheralded.

Good reasons to keep the VF patient on Bretylol follow-up therapy!

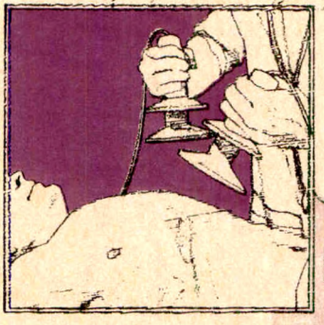
1. Bretylol raises the VF threshold almost three times control, protecting the heart from fibrillation.[1]*
   No other agent has this dramatic effect.
2. Bretylol also suppresses reentry, a major cause of VF by helping to equalize the electrophysiological differences between injured and normal ventricular tissue.[2]*
   No other agent can do this.

And, Bretylol offers added benefit in treating the acute episode, too.

Bretylol, a first-line agent in the acute control of VF, should be used in the very first stages of VF, as soon as cardiopulmonary resuscitation and countershock have been attempted. Bretylol not only raises the fibrillation threshold...it reduces the energy required for defibrillation.[3,4]* Another critical difference in the Bretylol mechanism of action.

That's why it makes sense to use Bretylol to maintain stabilization in the CCU, as well as in the first few minutes of acute VF episodes.

There are no contraindications to the use of Bretylol in VF. Hypotension and postural hypotension have been the most frequently reported adverse reactions. Consult brief summary of prescribing information on the following page.



For further information, please contact the Medical Services Department, American Critical Care, a division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, IL 60085, Phone 312/473-3000.

Bretylol...adds a different and unique dimension in control of ventricular fibrillation

American Critical Care

Bretylol®
(bretylium tosylate)

Brief summary of prescribing information

INDICATIONS—BRETYLOL is indicated in the prophylaxis and therapy of ventricular fibrillation.

BRETYLOL is also indicated in the treatment of life-threatening ventricular arrhythmias, such as ventricular tachycardia, that have failed to respond to adequate doses of a first-line antiarrhythmic agent, such as lidocaine.

Use of BRETYLOL should be limited to intensive care units, coronary care units or other facilities where equipment and personnel for constant monitoring of cardiac arrythmias and blood pressure are available.

Following injection of BRETYLOL there may be a delay of 20 minutes to 2 hours in the onset of antiarrhythmic action, although it appears to act within minutes in ventricular fibrillation. The delay in effect appears to be longer after intramuscular than after intravenous injection.

CONTRAINDICATIONS—There are no contraindications to use in treatment of ventricular fibrillation or life-threatening refractory ventricular arrhythmias.

WARNINGS—**1. Hypotension:** Administration of BRETYLOL regularly results in postural hypotension, subjectively recognized by dizziness, lightheadedness, vertigo or faintness. Some degree of hypotension is present in about 50% of patients while they are supine. Hypotension may occur at doses lower than those needed to suppress arrhythmias.

> Patients should be kept in the supine position until tolerance to the hypotensive effect of BRETYLOL develops. Tolerance occurs unpredictably but may be present after several days.

Hypotension with supine systolic pressure greater than 75 mm Hg need not be treated unless there are associated symptoms. If supine systolic pressure falls below 75 mm Hg, an infusion of dopamine or norepinephrine may be used to raise blood pressure. When catecholamines are administered, a dilute solution should be employed and blood pressure monitored closely because the pressor effects of the catecholamines are enhanced by BRETYLOL. Volume expansion with blood or plasma and correction of dehydration should be carried out where appropriate.

2. Transient Hypertension and Increased Frequency of Arrhythmias: Due to the initial release of norepinephrine from adrenergic postganglionic nerve terminals by BRETYLOL, transient hypertension or increased frequency of premature ventricular contractions and other arrhythmias may occur in some patients.

3. Caution During Use with Digitalis Glycosides: The initial release of norepinephrine caused by BRETYLOL may aggravate digitalis toxicity. When a life-threatening cardiac arrhythmia occurs in a digitalized patient, BRETYLOL should be used only if the etiology of the arrhythmia does not appear to be digitalis toxicity and other antiarrhythmic drugs are not effective. Simultaneous initiation of therapy with digitalis glycosides and BRETYLOL (bretylium tosylate) should be avoided.

4. Patients with Fixed Cardiac Output: In patients with fixed cardiac output (i.e., severe aortic stenosis or severe pulmonary hypertension) BRETYLOL should be avoided since severe hypotension may result from a fall in peripheral resistance without a compensatory increase in cardiac output. If survival is threatened by the arrhythmia, BRETYLOL may be used but vasoconstrictive catecholamines should be given promptly if severe hypotension occurs.

USE IN PREGNANCY—The safety of BRETYLOL in human pregnancy has not been established. However, as the drug is intended for use only in life-threatening situations, it may be used in pregnant women when its benefits outweigh the potential risk to the fetus.

USE IN CHILDREN—The safety and efficacy of this drug in children has not been established. BRETYLOL has been administered to a limited number of pediatric patients, but such use has been inadequate to define fully proper dosage and limitations for use.

PRECAUTIONS—**1. Dilution for Intravenous Use:** BRETYLOL should be diluted (one part BRETYLOL with four parts of Dextrose Injection, USP or Sodium Chloride Injection, USP) prior to intravenous use. Rapid intravenous administration may cause severe nausea and vomiting. Therefore, the diluted solution should be infused over a period greater than 8 minutes. In treating existing ventricular fibrillation BRETYLOL should be given as rapidly as possible and may be given without dilution.

2. Use of Various Sites for Intramuscular Injection: When injected intramuscularly, not more than 5 ml should be given in a site, and injection sites should be varied since repeated intramuscular injection into the same site may cause atrophy and necrosis of muscle tissue, fibrosis, vascular degeneration and inflammatory changes.

3. Reduce Dosage in Impaired Renal Function: Since BRETYLOL is excreted principally via the kidney, the dosage interval should be increased in patients with impaired renal function.

ADVERSE REACTIONS—Hypotension and postural hypotension have been the most frequently reported adverse reactions (see Warnings section). Nausea and vomiting occurred in about three percent of patients, primarily when BRETYLOL was administered rapidly by the intravenous route (see Precautions section). Vertigo, dizziness, light-headedness and syncope, which sometimes accompanied postural hypotension, were reported in about 7 patients in 1000.

Bradycardia, increased frequency of premature ventricular contractions, transitory hypertension, initial increase in arrhythmias (see Warnings section), precipitation of anginal attacks, and sensation of substernal pressure have also been reported in a small number of patients, i.e., approximately 1-2 patients in 1000.

Renal dysfunction, diarrhea, abdominal pain, hiccups, erythematous macular rash, flushing, hyperthermia, confusion, paranoid psychosis, emotional lability, lethargy, generalized tenderness, anxiety, shortness of breath, diaphoresis, nasal stuffiness and mild conjunctivitis, have been reported in about 1 patient in 1000. The relationship of BRETYLOL administration to these reactions has not been clearly established.

HOW SUPPLIED—NDC 0094-0012-10: 10 ml ampul containing 500 mg bretylium tosylate in Water for Injection, USP pH adjusted, when necessary, with dilute hydrochloric acid or sodium hydroxide. Sterile, non-pyrogenic.

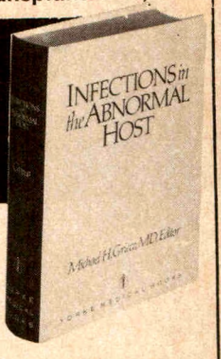
the knowledge of world-renowned specialists to help you understand, diagnose, and manage infections which strike patients with:

Diabetes / Alcoholism / Cancer / Drug Addiction / Rheumatic Disease / Uremia / Pulmonary Disease / Hepatic Insufficiency / Allograft Transplantation, etc.

INFECTIONS
IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color



Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy • Index

one for each patient in the U.S. who has been treated with Slow-K.*
No other slow-release potassium comes near that record of experience.
Slow-K®
potassium chloride slow-release tablets 8 mEq
Slow-release potassium chloride preparations should be reserved for patients who cannot tolerate, refuse to take or have compliance problems with liquid or effervescent potassium preparations, because of reports of intestinal and gastric ulceration and bleeding with slow-release KCl preparations.
*Based on courses of therapy through 1981. Data on file, CIBA Pharmaceutical Company.
Please see next page for brief Prescribing Information.
CIBA

SLOW-K®
potassium chloride **slow-release tablets**

Brief Summary of Prescribing Information

DESCRIPTION
Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS
BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.
1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS
Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).
Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.
All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS
Hyperkalemia: In patients with impaired mechanisms for excreting potassium the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.
The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.
Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.
Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains approximately one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.
Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS
The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

ADVERSE REACTIONS
The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.
One of the most severe adverse effects is hyperkalemia (see Contraindications, Warnings and Overdosage). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION
The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.
Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

Congestive Heart Failure

Mechanisms, Evaluation and Treatment
Dean T. Mason, M.D.

This rare treatment of such a multifaceted subject provides an unusual opportunity for the busy clinician to add to his knowledge in a minimum amount of time. Any area of immediate interest can be rapidly located and as much data as needed can be quickly extracted. The concentration on improved clinical management will be appreciated by every internist, cardiologist, generalist, and any professional involved in cardiovascular medicine.

Dean Mason, President of the American College of Cardiology, has organized this monograph within the three areas relevant to an understanding of congestive heart failure: *mechanisms, evaluation* and *treatment*. Fifty-six recognized authorities have been assembled by Dr. Mason, each contributing their expertise to make this book the foremost text covering the highly important and common disorders of abnormal heart function.

This presentation of recent advances in basic research and clinical progress has been highly acclaimed for its major contribution to the improvement of patient care. We invite you to see if you don't agree. Order and take 30 days to look over the book. If you're not totally satisfied, return it.

About the author . . . Dean T. Mason, M.D.

Professor of Medicine, Professor Physiology, Chief of Cardiovascular Medicine, University of California, School of Medicine, Davis.

President, American College of Cardiology; President, Western Society for Clinical Research.

Member of the American Board of Internal Medicine Cardiovascular Diseases.

Has authored more than 400 original articles on cardiovascular science and clinical cardiology.

Serves on the editorial boards of The American Journal of Cardiology, The Journal of Clinical Investigation, Circulation, Chest, Clinical Pharmacology and Therapeutics, Catheterization and Cardiovascular Diagnosis, and Heart and Lung.

Recipient of Experimental Therapeutics Award in 1973 from the American Society of Pharmacology and Experimental Therapeutics, the Research Awards in 1965 from the American Therapeutic Society, and the Theodore and Susan B. Cummings Humanitarian Awards in 1972, 1973, and 1975 from the U.S. State Department and the American College of Cardiology.

YORKE MEDICAL BOOKS Box C-757, Brooklyn, N.Y. 11205

Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by,
Lawrence H. Cohn, MD,
Vincenzo Gallucci, MD

The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

Contributors from virtually every major cardiovascular center in the world that has had any meaningful experience with cardiac bioprosthetic valves participated in this symposium where 45 papers were presented in 8 categories.

ISBN 0-914316-34-6, 596pp., illus., 1982, $65.00

Atlas Of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Foreword by David H. Spodick, MD

Dr. Alfredo Palacio has drawn on his rich experience to produce an atlas which presents in the simplest, most direct way possible the broadest range of normal and abnormal 2-dimensional echograms. Its excellent illustrations are complemented by beautiful drawings and supplemented by diagrams and explanatory texts which transcend the usual collection of illustrative material to explain methodology and provide the reader with a true "how-to-do-it" text. The descriptions and detailed illustrations in its technical sections should ensure the superior level of performance of echocardiographic techniques that is a *sine qua non* for good results.

Your angina patients* can become more active now...with PROCARDIA protection. They'll be pain-free more of the time[1] and find their need for nitroglycerin greatly reduced.[2] They'll be able to work harder, exercise more.[3] And be more active participants in their own lives once again.

feeling better...doing more

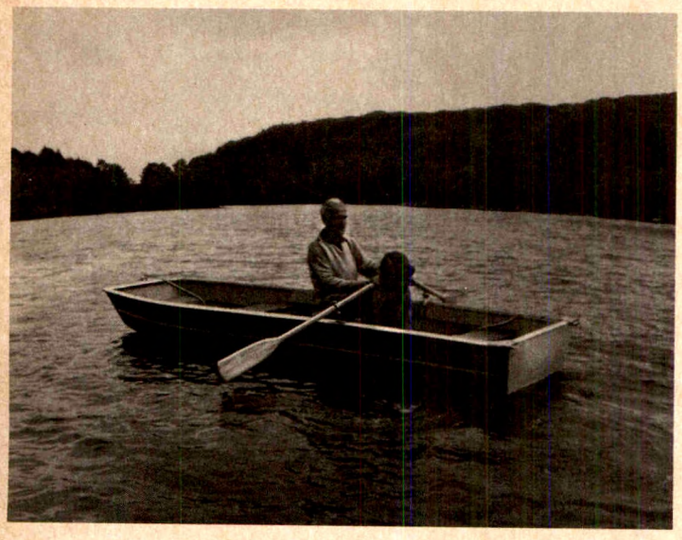
PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

*Procardia is indicated for the management of:

- Confirmed vasospastic angina.
- Angina where the clinical presentation suggests a possible vasospastic component.
- Chronic stable angina without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or nitrates or who cannot tolerate these agents. In chronic stable angina (effort-associated angina) Procardia has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Please see PROCARDIA® brief summary on next page.

feeling better...doing more



PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

–Usual effective dosage is 30-60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because Procardia decreases peripheral vascular resistance, careful monitoring of blood pressure during initial administration and titration is suggested. Close observation is especially recommended for patients taking medication known to lower blood pressure.

–Offers a favorable safety profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

CARD

The Cardiac Doppler system expands conventional echocardiography by providing noninvasive assessment of flow velocities through all four heart valves. It is all you need to confirm stenotic or regurgitant valvular disease.

- Color spectral patterns grade the degree of valve stenosis and turbulence.
- Valve cross-sectional areas can be derived from pressure gradient half-times.
- Color spectral patterns grade the degree of regurgitation. Valve prolapse is identified through the presence and timing of regurgitation.

- Detects th prosthetic Monitors v
- Color spec
- Displays E correlation patterns.
- Computes volume and

The ECG cartridge with 50 lives.

DEL MAR AVIONICS

Conventional 24-hour Holter reel tapes have less than 9 lives. And cassettes are recommended only for single use.

But our advanced design, four-channel cartridge, when used with the Series 449 Electrocardiocorder® Systems, may be erased and re-used for up to 50 ambulatory recordings.

The reasons?

The cartridge has been specifically designed with extended tape life in mind. Combining the convenience of a cassette with the accuracy of a reel-to-reel design, the cartridge tape can be manipulated at today's high scanning speeds with exact precision. Moreover, precise data management can be attained without tape stretching or twisting, increasing tape life at least ten-fold.

Precise time coding, using a proprietary digital encoding process, ensures timing accuracy to within one second throughout the entire 24-hour recording. And the magnetic characteristics of the tape itself are matched exactly to the dynamic range of our analyzers. Total system compatibility gives you optimal fidelity.

And if that's not enough, one of the cartridge channels can be used to record ambulatory blood pressure, further extending your diagnostic capability.

For more details on the four-channel cartridge that gives you added life, superior fidelity and BP capability, contact Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714, Telephone (714) 549-1500, or call toll free at (800) 854-0481, (in California 800/432-8446), Telex: 68-5621.

*Test data available upon request.

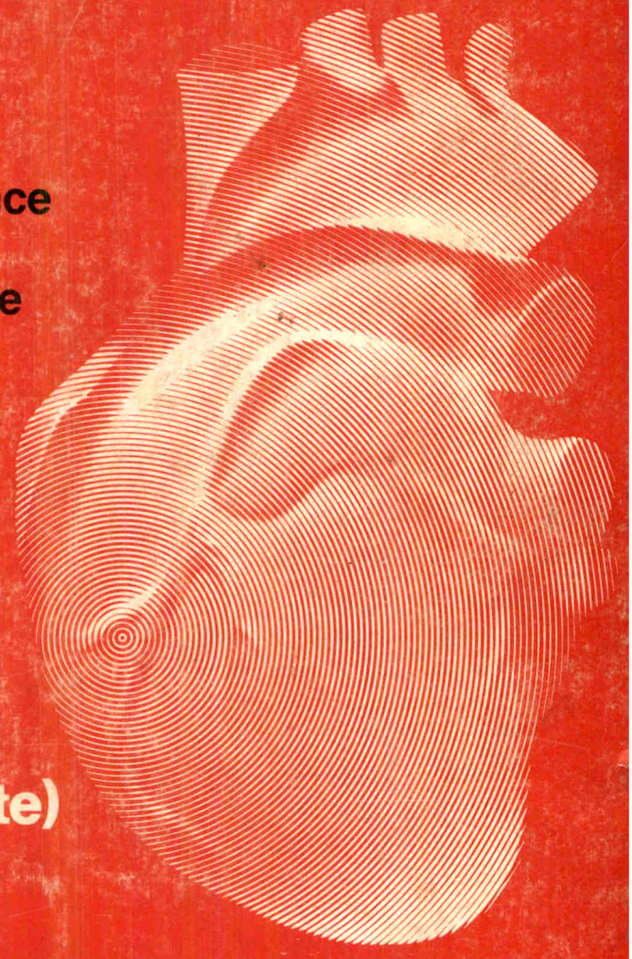
The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.



CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations.
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digoxin (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: The drug should be used with caution due to excretion of the quinidine in breast milk. ADVERSE REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/or disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTESTINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricular tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMATOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intense pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribing Information.

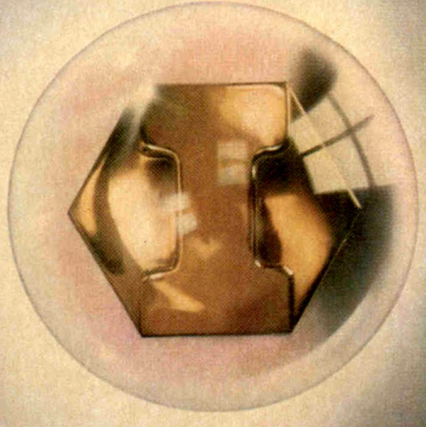
Thallium-201 perfusion scan showing left ventricle of patient with angina.

ANGINA PROTECTION AND MORE

INDERAL represents core therapy for angina... unlike calcium antagonists and other beta blockers, only INDERAL is indicated for angina prophylaxis, a wide range of supraventricular arrhythmias and hypertension.

INDERAL, used early, reduces myocardial oxygen demand and protects against ischemia. INDERAL slows heart rate, decreases contractility, and lowers elevated blood pressure. Use INDERAL early in the treatment of angina to prevent ischemia-induced pains and to protect the heart against coexisting arrhythmias...and their consequences.



INDERAL®
(PROPRANOLOL HCl)

COMPREHENSIVE CARDIOVASCULAR PROTECTION

Please see next page for brief summary of prescribing information.

INDERAL®
(PROPRANOLOL HCl)

CORE THERAPY FOR ANGINA.

TM

The appearance of these tablets is a trademark of Ayerst Laboratories.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

Propranolol hydrochloride is contraindicated in 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. Propranolol acts selectively without abolishing the inotropic action of digitalis on the heart muscle (i.e., that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by propranolol's negative inotropic effect. The effects of propranolol and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during propranolol therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of propranolol therapy. Therefore, when discontinuance of propranolol is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when propranolol is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If propranolol therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute propranolol therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long-term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since propranolol is a competitive inhibitor of beta-receptor agonists, its effects can be reversed by administration of such agents, e.g., isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), propranolol should be administered with caution since it may block chodilation produced by endogenous and exogenous catecholamine stimulation o receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, propranolol may prevent the appearance of premonito and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is e important to keep in mind in patients with labile diabetes. Hypoglycemic attacks ma accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of propranolol in human pregnancy has not b established. Use of any drug in pregnancy or women of childbearing potential requ the possible risk to mother and/or fetus be weighed against the expected therapeu fit. Embryotoxic effects have been seen in animal studies at doses about 10 times th mum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine-depleting drugs such as reserpine should be clos observed if propranolol is administered. The added catecholamine-blocking action drug may then produce an excessive reduction of the resting sympathetic nervous a Occasionally, the pharmacologic activity of propranolol may produce hypotension a marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotensio

As with any new drug given over prolonged periods, laboratory parameters shoul observed at regular intervals. The drug should be used with caution in patients with renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hy sion; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thromb nic purpura. *Central Nervous System:* lightheadedness; mental depression manifes insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome charac by disorientation for time and place, short term memory loss, emotional lability, slight clouded sensorium, and decreased performance on neuropsychometrics. *Gastroin* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, teric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and tory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrom cytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. mucocutaneous reactions involving the skin, serous membranes and conjunctivae r for a beta blocker (practolol) have not been conclusively associated with propranolo *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenas

HOW SUPPLIED

INDERAL (propranolol hydrochloride)

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprir "INDERAL 10," contains **10 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046 81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421

—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinte "INDERAL 20," contains **20 mg** propranolol hydrochloride, in bottles of 100 (NDC 004 81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422

—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinte "INDERAL 40," contains **40 mg** propranolol hydrochloride, in bottles of 100 (NDC 004 81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424

—Each hexagonal-shaped, pink, scored tablet is embossed with an "I" and imprinted "INDERAL 60," contains **60 mg** propranolol hydrochloride, in bottles of 100 (NDC 004 81) and 1,000 (NDC 0046-0426-91). Also in unit dose package of 100 (NDC 0046-0426

—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinte "INDERAL 80," contains **80 mg** propranolol hydrochloride, in bottles of 100 (NDC 004 81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

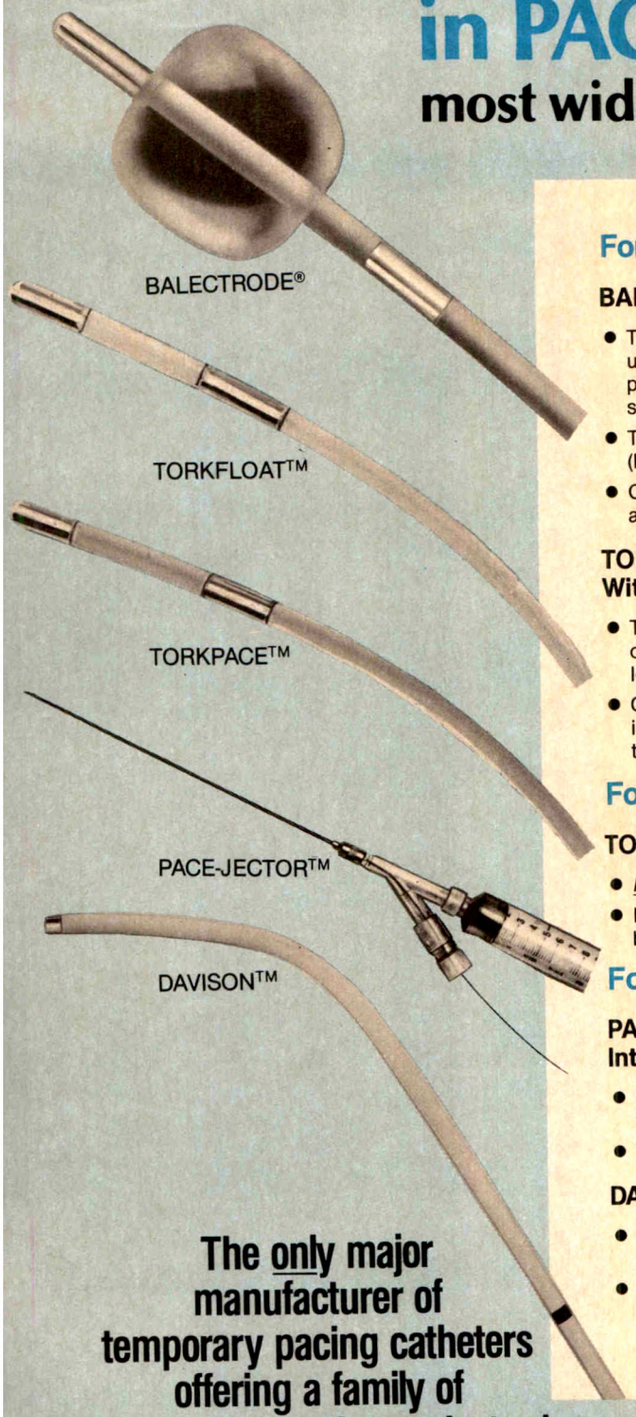
ELECATH®...Leading the way in PACING CATHETERS

most widely used...widest selection



For Placement *without* Fluoroscopy

BALECTRODE® Balloon Flow-Directed Pacing Kit

- The *only* major manufacturer of Balloon Flow-Directed pacing products to offer non-corroding *platinum* electrodes to assure optimal physiological response, and to prevent the migration effect seen in stainless steel electrodes.
- Two French sizes are available: 3 French (KBE1) and 5 French (KBE2) for various patient physiological requirements.
- Complete sterile kit, consisting of an introducer, shielded EKG adapter, and vented syringe for exact, accurate balloon inflation.

TORKFLOAT™ Semi-Floating Pacing Kit With 1:1 Torque Response

- The *only* major manufacturer of semi-floating pacing products to offer non-corroding *platinum* electrodes to assure optimal physiological response.
- Complete kit includes pacing catheter with centimeter markings, introducer and sterile shielded EKG adapter for artifact-free EKG tracing, for confirmation of placement.

For Placement *with* Fluoroscopy

TORKPACE™ Standard Pervenous Pacing Probes

- *Platinum* electrodes to assure optimal physiological response.
- Hybrid inner core design provides a semi-flexible catheter tip for better flexibility for permanence of position and safety.

For Emergency Pacing

PACE-JECTOR™—The Unique Dual Purpose Pacing And Intracardiac Medication System (11-KPJ1)

- Direct electrical stimulation and/or pharmacological manipulation of the unresponsive myocardium is immediately available.
- The pacing stylet is *pre-loaded* for simple intraventricular placement.

DAVISON™—Emergency Transvenous Pacing Lead (11-KTFD)

- Capture achieved as soon as the proximal electrode emerges from the introducer sheath.
- *Platinum* electrodes located 19cm apart assure conduction system stimulation regardless of catheter tip position in the ventricle.

The only major manufacturer of temporary pacing catheters offering a family of non-corrosive platinum electrodes.

In Hypertension*...When You Need to Conserve K^+

Every Step of the Way

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

†Step 1 usually consists of an initial phase (a diuretic alone), a titration phase (dosage adjustment and/or addition of a K^+ supplement or K^+-sparing agent), and a maintenance phase (a diuretic alone or in combination with a K^+ supplement or K^+-sparing agent).

Serum K^+ and BUN should be checked periodically (see Warnings).

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

* **WARNING**
This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this comoination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, 'Dyazide' should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on 'Dyazide' when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with 'Dyazide'. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with 'Dyazide', but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and 'Dyazide' should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. 'Dyazide' should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances; postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on 'Dyazide', although a causal relationship has not been established.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

NOW A MATTER OF SIMPLE ADDITION

ATL INTRODUCES REGISTREX™ 1000 DIGITAL SUBTRACTION SYSTEM

Connect, disconnect, move, and reconnect as your needs dictate.

Now ATL gives you high-quality vascular images with a *completely digital* DSA system that greatly simplifies interfacing requirements. The new Registrex 1000 System is a single, compact, movable DSA unit—ready to connect, disconnect, move, and reconnect to meet patient load and room scheduling requirements. It lets you add complete digital subtraction capability without changing your existing video camera, without using a three-phase x-ray generator or high-power x-ray tube, and without the major additional costs of other add-on systems.

Selectable Interval-Imaging — the best of both technologies.

This remarkably simple interface is made possible by Selectable Interval-Imaging. Unique to ATL, this technology incorporates the advantages of two familiar technologies and eliminates the disadvantages of both. It combines the benefits of matched-filter processing remasking, and reregistration—valuable features of pulsed technology required to reduce patient-motion artifacts and achieve high image quality—with the easy interface and low-mA (2 to 50) operation of continuous technology.

What does this mean to you?

"Pulsed" technology gives you the important processing advantages of remasking and reregistration. These systems, however, require special video cameras, high-power x-ray equipment, heavy tube loading, and high-mA capability. On the other hand, "continuous" technology permits the use of existing video cameras and low-power x-ray equipment but can't achieve high image quality because it lacks the remasking and reregistration essential to remove patient-motion artifacts. Now the Registrex 1000 System gives you the best of both technologies with none of the disadvantages.

The ATL REGISTREX 1000 System gives you a unique combination of features.

Selectable Interval-Imaging. Complete remasking and reregistration capability *and* superb image quality with your existing video camera and low-power, low-mA x-ray operation.

Total View. Simultaneously viewed multi-image remasking capability—unique to ATL.

Flexi-Mask. Any image selected as the mask is simultaneously subtracted from all of the other images, rapidly identifying the best possible image and reducing the need for reruns due to gross misregistration. Flexi-Mask is unique to ATL.

Image Reregistration. The capability to reregister the image over preselected regions. Automatic reregistration will be achieved through software upgrade using the Registrex System's

electronics to perform subpixel image translation.

Matched-Filter Processing. Leading-edge processing technology achieving signal-to-noise ratios up to 4000:1 from existing video chains. Unique to ATL.

Low-mA Imaging. For a simple interface with your existing video cameras and single-phase x-ray generator. Unit is easily moved for hookup to different systems.

Gray-Scale Latitude. 16-bit image memories permit data acquisition with signal-to-noise ratios up to 4000:1.

The simplest way to have DSA today.

The Registrex 1000 System is designed to give you maximum information in the most efficient way. It permits significantly reduced radiation dosage and/or contrast media requirements—and it reduces costs as well. Because you will not have to purchase a new video camera or upgrade your existing x-ray equipment, you will save major additional costs required with other add-on systems.

If you've been waiting to add this exciting imaging technique to your diagnostic resources—it's now a simple matter. The Registrex 1000 System is ready and waiting for you.

For a demonstration of the Registrex 1000 System—or more information—please call 800-426-2670; or write, Advanced Technology Laboratories, Inc., P.O. Box 6639, Bellevue, WA 98003-0639.

We're ready to introduce you to the simplest way to have DSA today.

1535 **Summary.** James R. Zuberbuhler

VALVULAR HEART DISEASE

1537 **Trial of Combined Warfarin Plus Dipyridamole or Aspirin Therapy in Prosthetic Heart Valve Replacement: Danger of Aspirin Compared With Dipyridamole.** James H. Chesebro, Valentin Fuster, Lila R, Elveback, Dwight C. McGoon, James R. Pluth, Francisco J. Puga, Robert B. Wallace, Gordon K. Danielson, Thomas A. Orszulak, Jeffrey M. Piehler, and Hartzell V. Schaff

1542 **Early Detection of Left Ventricular Dysfunction in Chronic Aortic Regurgitation as Assessed by Contrast Angiography, Echocardiography, and Rest and Exercise Scintigraphy.** Robert L. Huxley, Andrew Gaffney, James R. Corbett, Brian G. Firth, Ronald Peshock, Pascal Nicod, James S. Rellas, George Curry, Samuel E. Lewis, and James T. Willerson

1551 **Effect of Elevating the Wrist on the Radial Pulse in Aortic Regurgitation: Corrigan Revisited.** Carole A. Warnes, Peter C. Harris, and Harry W. Fritts

THERAPY

1554 **Effects of Disopyramide on Left Ventricular Function: Assessment by Radionuclide Cineangiography.** John Gottdiener, Robert Dibianco, Richard Bates, Bertram J. Sauerbrunn, and Ross D. Fletcher, *With the technical assistance of* Rod Noss and Ann Rusk

BRIEF REPORTS

1559 **Septal Ischemia as a Mechanism of Complete Atrioventricular Block: Demonstration by Thallium Scintigraphy.** Avraham Theodore Weiss, Yonatham Hasin, and Mervyn Samuel Gotsman

1560 **Atrial Septostomy as Palliative Therapy for Refractory Primary Pulmonary Hypertension.** Stuart Rich and Wilfred Lam

1561 **Fatal Small Bowel Obstruction After Pacemaker Generator Implantation in the Abdominal Wall.** Meir Mazuz, Natesa G. Pandian, and Richard E. Kerber

1562 **Five Coronary Ostia: Duplicate Left Anterior Descending and Right Conus Coronary Arteries.** Bruce F. Waller

1563 **Left Atrial Mass: Diagnostic Value of Transesophageal 2-Dimensional Echocardiography and Indium-111 Platelet Scintigraphy.** Michael D. Ezekowitz, Eileen O. Smith, Robert Rankin, Lynn H. Harrison, Jr., and Henry F. Krous

1565 **LETTERS**

INSTRUCTIONS TO AUTHORS on page 1536

INDEX TO ADVERTISERS on page A46

Indications: Premature atrial and ventricular contractions, aproxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, paroxysmal ventricular tachycardia when not associated with complete heartblock, maintenance therapy after electrical conversion of atrial fibrillation and/or flutter.

Contraindications: Intraventricular conduction defects. A-V block. Idiosyncrasy or hypersensitivity.

Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.

Warning: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio and resulting in extremely rapid ventricular rate.

Precautions: All the precautions applying to regular quinidine therapy apply to the Extentab form. Use with care in patients with severe congestive failure, renal insufficiency or with digitalis intoxication.

Patients should be carefully observed for signs of toxicity: e.g., (1) allergy or idiosyncrasy, such as febrile reactions, skin eruptions, and thrombocytopenia (extremely rare); (2) "cinchonism," such as tinnitus, blurred vision, dizziness, light-headedness, and tremor; (3) G.I. symptoms (nausea, vomiting, diarrhea, and colic); (4) cardiotoxic effects such as ventricular extrasystoles occurring at the rate of one or more every 6 normal beats, an increase of the QRS complex of 50% or more, a complete A-V block, or ventricular tachycardia.

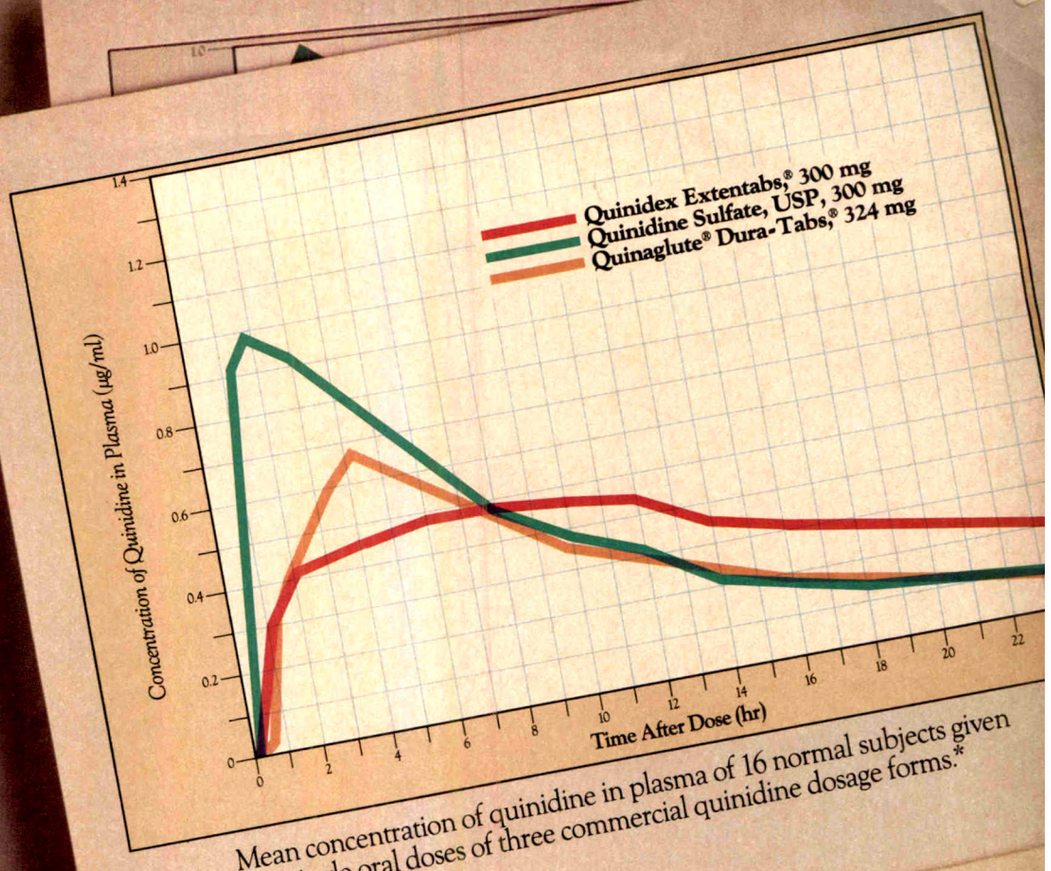
NOTE: The development of "cinchonism" is not usually sufficient reason for terminating quinidine therapy. G.I. symptoms can also be minimized by giving the drug with food.

Adverse Reactions: Cases of quinidine-induced hypoprothrombinemic hemorrhage in patients on chronic anticoagulant drug therapy have been reported.

Dosage: Two Quinidex Extentabs every 8 to 12 hours.

How Supplied: White sugar-coated Extentabs in bottles of 100 (NDC 0031-6649-63) and 250 (NDC 0031-6649-67) and Dis-co® Unit Dose Packs of 100 (NDC 0031-6649-64).

Rev. Dec. 1981



Mean concentration of quinidine in plasma of 16 normal subjects given single oral doses of three commercial quinidine dosage forms.*

Consider The Evidence For Quinidex (Quinidine Sulfate, USP), 300 mg Extentabs®

- The convenience of b.i.d. dosage*
- Up to 12 hours of smooth, sustained release
- Relative bioavailability equal to Quinidine Sulfate Tablets, USP
- Contains 48 mg more active quinidine than the leading gluconate product

*Some patients may require a t.i.d. dosage schedule.

For the proof, ask your Robins representative for a copy of the controlled crossover study. Or write S. Tisdale, M.D., 1211 Sherwood Avenue, Richmond, Va. 23220.

Oslerian Advice

In 1959 I purchased from Old Hickory Bookshop in Brinklow, Maryland, a book entitled *Sir William Osler, Bart., Brief Tributes to His Personality, Influence and Public Service Written by His Friends, Associates and Former Pupils, In Honor of His Seventieth Birthday and First Published in The Bulletin of The Johns Hopkins Hospital for July, 1919.* This 167-page book, which also contains Osler's bibliography, has since been a steady companion of mine. My favorite chapter was written by his former Johns Hopkins' Chief Resident, William S. Thayer, who described the third heart sound, and is entitled "Osler, The Teacher." In it, Thayer paraphrases comments of Osler apparently reiterated many times during rounds and other discussions. The comments are as appropriate 64 years later as when they were recorded by Thayer:

Observe, record, tabulate, communicate.

Use your five senses. The art of the practice of medicine is to be learned only by experience; 'tis not an inheritance; it cannot be revealed. Learn to see, learn to hear, learn to feel, learn to smell, and know that by practice alone can you become expert. Medicine is learned by the bedside and not in the classroom. Let not your conceptions of the manifestations of disease come from words heard in the lecture room or read from the book. See, and then reason and compare and control. But see first. No two eyes see the same thing. No two mirrors give forth the same reflection. Let the word be your slave and not your master.

Live in the ward. Do not waste the hours of daylight in listening to that which you may read by night. But when you have seen, read. And when you can, read the original descriptions of the masters who, with crude methods of study, saw so clearly.

Record that which you have seen; make a note at the time; do not wait. "The flighty purpose never is o'ertook, unless the deed go with it."

Memory plays strange pranks with facts. The rocks and fissures and gullies of the mountain-side melt quickly into the smooth, blue outlines of the distant panorama. Viewed through the perspective of memory, an unrecorded observation, the vital details long since lost, easily changes its countenance and sinks obediently into the frame fashioned by the fancy of the moment.

Always note and record the unusual. Keep and compare your observations. Communicate or publish short notes on anything that is striking or new. Do not waste your time in compilations, but when your observations are sufficient, do not let them die with you. Study them, tabulate them, seek the points of contact which may reveal the underlying law. Some things can be learned only by statistical comparison. If you have the good fortune to command a large clinic, remember that one of your chief duties is the tabulation and analysis of the carefully recorded experience.

The collection and study of your own observations is much, but he who works in his own small compartment leads, after all, a restricted and circumscribed life. Go out among your fellows, and learn of them. The good observer is not limited to the large hospital. The modest country doctor may furnish you the vital link in your chain, and the simple rural practitioner is often a very wise man.

Respect your colleagues. Know that there is no more high-minded body of men than the medical profession. Do not judge your confrères by the reports of patients, well meaning, perhaps, but often strangely and sadly misrepresenting. Never let your tongue say a slighting word of a colleage [sic]. It is not for you to judge. Let not your ear hear the sound of your voice raised in unkind criticism or ridicule or condemnation of a brother physician. If you do, you can never again meet that man face to face. Wait. Try to believe the best. Time will generally show that the words you might have spoken would have been unjust, would have injured a good man, and lost you a friend, and then—silence is a powerful weapon.

When you have made and recorded the unusual or original observation, or when you have accomplished a piece of research in laboratory or ward; do not be satisfied with a verbal communication at a medical society. Publish it. Place it on permanent record as a short, concise note. Such communications are always of value.

Mix with your colleagues; learn to know them. But in your relations with the profession and with the public, in everything that pertains to medicine, consider the virtues of taciturnity. Look out. Speak only when you have something to say. Commit yourself only when you can and must. And when you speak, assert only that of which you know. Beware of

words—they are dangerous things. They change color like the chameleon, and they return like a boomerang. Do you know the story of the young physician, about to enter practice, who was sent by his father to his old friend, Sir William Stokes, for advice? A pleasant conversation, and, at the doorway, a last word: "Charley, don't say too much." Then, at the gate, a voice: "Charley, come back a minute; I'm very fond of you, my boy; don't *do* too much."

"Don't do too much." Remember how much you do not know. Do not pour strange medicines into your patients. Our greatest assistance is given by simple physical and mental means, and by the careful employment of such drugs as have been adequately studied, with regard to the action of which we have real information. Do not rashly use every new product of which the peripatetic siren sings. Consider what surprising reactions may occur in the laboratory from the careless mixing of unknown substances. Be as considerate of your patient and yourself as you are of the test-tube.

Familiarize yourself with the work of others and never fail to give credit to the precursor. Let every student have full recognition for his work. Never hide the work of others under your own name. Should your assistant make an important observation, let him publish it. Through your students and your disciples will come your greatest honor.

Be prompt at your appointments; that is always possible. Many are always late at a consultation; few miss a train. There is no excuse for tardiness.

Live a simple and a temperate life, that you may give all your powers to your profession. Medicine is a jealous mistress; she will be satisfied with no less.

Save the fleeting minute; do not stop by the way. Learn gracefully to dodge the bore. Strike first and quickly, and before he has recovered from the blow, be gone; 'tis the only way. . . .

If you can practice consistently all this, . . . and then, if you can bring into corridor and ward a light, springing step, a kindly glance, a bright word to every one you meet, arm passed within arm or thrown over the shoulder of the happy student or colleague; a quick, droll, epigrammatic question, observation or appellation that puts the patient at his ease or brings a pleased blush to the face of the nurse; an apprehension that grasps in a minute the kernel of the situation, and a memory teeming with instances and examples that throw light on the question; an unusual power of succinct statement and picturesque expression, exercised quietly, modestly and wholely without sensation; if you can bring into the lecture room an air of perfect simplicity and directness, and, behind it all, have an ever-ready store of the most apt and sometimes surprising interjections that so light up and emphasize that which you are setting forth that no one in the room can forget it; if you can enter the sick-room with a song and an epigram, an air of gaiety, an atmosphere that lifts the invalid instantly out of his ills, that produces in the waiting hypochondriac so pleasing a confusion of thought that the written list of questions and complaints, carefully compiled and treasured for the moment of the visit, is almost invariably forgotten; if the joy of your visit can make half a ward forget the symptoms that it *fancied* were important, until you are gone; if you can truly love your fellow, and, having said evil of no man, be loved by all; if you can select a wife with a heart as big as your own, whose generous welcome makes your tea-table a Mecca; . . . if you can do all this, you may begin to be to others the teacher that "the chief" is to us!

one-tablet-a-day dosage and...

cardioselectivity*

ONE TABLET A DAY

TENORMIN®

(atenolol)

Tablets 50 mg

*Cardioselectivity denotes a relative preference for β₁ receptors, located chiefly in cardiac tissue. This preference is not absolute.

See last page of this advertisement for brief summary of prescribing information.

STUART PHARMACEUTICALS

TENORMIN® (atenolol)

A beta$_1$-selective blocking agent for hypertension.

INDICATIONS AND USAGE: TENORMIN (atenolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide-type diuretic.

CONTRAINDICATIONS: TENORMIN is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure: Sympathetic stimulation is necessary in supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, TENORMIN should be administered cautiously. Both digitalis and atenolol slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, TENORMIN therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents in patients with coronary artery disease, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Therefore, such patients should be cautioned against interruption of therapy without the physician's advice. Even in the absence of overt angina pectoris, when discontinuation of TENORMIN is planned, the patient should be carefully observed and should be advised to limit physical activity to a minimum. TENORMIN should be reinstated if withdrawal symptoms occur.

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASE SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, TENORMIN may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute the lowest possible dose of TENORMIN should be used, with therapy initiated at 50 mg and a beta$_2$-stimulating agent (bronchodilator) made available. If dosage must be increased, dividing the dose should be considered in order to achieve lower peak blood levels.

Anesthesia and Major Surgery: As with all beta-receptor blocking drugs it may be decided to withdraw TENORMIN before surgery. In this case, 48 hours should be allowed to elapse between the last dose and anesthesia. If treatment is continued, care should be taken when using anesthetic agents which depress the myocardium, such as ether, cyclopropane, and trichloroethylene.

TENORMIN, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects on the heart can be reversed by administration of such agents (eg, dobutamine or isoproterenol with caution—see OVERDOSAGE). Manifestations of excessive vagal tone (eg, profound bradycardia, hypotension) may be corrected with atropine (1-2 mg I.V.).

Diabetes and Hypoglycemia: TENORMIN should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected. TENORMIN does not potentiate insulin-induced hypoglycemia and, unlike nonselective beta blockers, does not delay recovery of blood glucose to normal levels.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (eg, tachycardia) of hyperthyroidism. Abrupt withdrawal of beta blockade might precipitate a thyroid storm; therefore, patients suspected of developing thyrotoxicosis from whom TENORMIN therapy is to be withdrawn should be monitored closely.

PRECAUTIONS: Impaired Renal Function: The drug should be used with caution in patients with impaired renal function (see DOSAGE AND ADMINISTRATION).

Drug Interactions: Catecholamine-depleting drugs (eg, reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with TENORMIN plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Should it be decided to discontinue therapy in patients receiving beta blockers and clonidine concurrently, the beta blocker should be discontinued several days before the gradual withdrawal of clonidine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Two long-term (maximum dosing duration of 18 or 24 months) rat studies and one long-term (maximum dosing duration of 18 months) mouse study, each employing dose levels as high as 300 mg/kg/day or 150 times the maximum recommended human dose, did not indicate a carcinogenic potential in rodents. Results of various mutagenicity studies support this finding.

Fertility of male or female rats (evaluated at dose levels as high as 200 mg/kg/day or 100 times the maximum recommended human dose) was unaffected by atenolol administration.

Animal Toxicology: Chronic studies performed in animals have revealed the occurrence of vacuolation of epithelial cells of Brunner's glands in the duodenum of both male and female dogs at all tested dose levels of atenolol (starting at 15 mg/kg/day or 7.5 times the maximum recommended human dose) and increased incidence of atrial degeneration of hearts of male rats at 300 mg but not 150 mg atenolol/kg/day (150 and 75 times the maximum recommended human dose, respectively).

USAGE IN PREGNANCY: Pregnancy Category C. Atenolol has been shown to produce a dose-related increase in embryo/fetal resorptions in rats at doses equal to or greater than 50 mg/kg or 25 or more times the maximum recommended human dose. Although similar effects were not seen in rabbits, the compound was not evaluated in rabbits at doses above 25 mg/kg or 12.5 times the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. TENORMIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not established to what extent this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving atenolol.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient. Frequency estimates were derived from controlled studies in which adverse reactions were either volunteered by the patient (U.S. studies) or elicited (eg, by checklist—foreign studies). The reported frequency of elicited adverse effects was higher for both TENORMIN and placebo-treated patients than when these reactions were volunteered. Where frequency of adverse effects for TENORMIN and placebo is similar, causal relationship is uncertain.

The following adverse-reaction data present frequency estimates in terms of percentages: first from the U.S. studies (volunteered side effects) and then from both U.S. and foreign studies (volunteered and elicited side effects):

U.S. STUDIES (% ATENOLOL-% PLACEBO):

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (0%-0.5%), postural hypotension (2%-1%), leg pain (0%-0.5%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (4%-1%), vertigo (2%-0.5%), light-headedness (1%-0%), tiredness (0.6%-0.5%), fatigue (3%-1%), lethargy (1%-0%), drowsiness (0.6%-0%), depression (0.6%-0.5%), dreaming (0%-0%)

GASTROINTESTINAL: diarrhea (2%-0%), nausea (4%-1%)

RESPIRATORY (See WARNINGS): wheeziness (0%-0%), dyspnea (0.6%-1%)

TOTALS U.S. AND FOREIGN STUDIES:

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (12%-5%), postural hypotension (4%-5%), leg pain (3%-1%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (13%-6%), vertigo (2%-0.2%), light-headedness (3%-0.7%), tiredness (26%-13%), fatigue (6%-5%), lethargy (3%-0.7%), drowsiness (2%-0.5%), depression (12%-9%), dreaming (3%-1%)

GASTROINTESTINAL: diarrhea (3%-2%), nausea (3%-1%)

RESPIRATORY (see WARNINGS): wheeziness (3%-3%), dyspnea (6%-4%)

MISCELLANEOUS: There have been reports of skin rashes and/or dry eyes associated with the use of beta-adrenergic blocking drugs. The reported incidence is small and, in most cases, the symptoms have cleared when treatment was withdrawn. Discontinuance of the drug should be considered if any such reaction is not otherwise explicable. Patients should be closely monitored following cessation of therapy.

POTENTIAL ADVERSE EFFECTS: In addition, a variety of adverse effects have been reported with other beta-adrenergic blocking agents, and may be considered potential adverse effects of TENORMIN (atenolol).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Fever, combined with aching and sore throat, laryngospasm and respiratory distress.

Central Nervous System: Reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation of time and place, short-term memory loss, emotional lability with slightly clouded sensorium, decreased performance on neuropsychometrics.

Gastrointestinal: Mesenteric arterial thrombosis, ischemic colitis.

Other: Reversible alopecia, Peyronie's disease, erythematous rash, Raynaud's phenomenon.

Miscellaneous: The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with TENORMIN during investigational use and foreign marketing experience. Furthermore, a number of patients who had previously demonstrated established practolol reactions were transferred to TENORMIN therapy with subsequent resolution or quiescence of the reaction.

OVERDOSAGE: To date, there is no known case of acute overdosage, and no specific information on emergency treatment of overdosage is available. The most common effects expected with overdosage of a beta-adrenergic blocking agent are bradycardia, congestive heart failure, hypotension, bronchospasm, and hypoglycemia.

In the case of overdosage, treatment with TENORMIN should be stopped and the patient carefully observed. TENORMIN can be removed from the general circulation by hemodialysis. In addition to gastric lavage, the following therapeutic measures are suggested if warranted:

Bradycardia: Atropine or another anticholinergic drug.

Heart Block (Second or Third Degree): Isoproterenol or transvenous cardiac pacemaker.

Congestive Heart Failure: Conventional therapy.

Hypotension (Depending on Associated Factors): Epinephrine rather than isoproterenol or norepinephrine may be useful in addition to atropine and digitalis.

Bronchospasm: Aminophylline, isoproterenol, or atropine.

Hypoglycemia: Intravenous glucose.

DOSAGE AND ADMINISTRATION: The initial dose of TENORMIN is 50 mg given as one tablet a day either alone or added to diuretic therapy. The full effect of this dose will usually be seen within one to two weeks. If an optimal response is not achieved, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Increasing the dosage beyond 100 mg a day is unlikely to produce any further benefit.

TENORMIN may be used alone or concomitantly with other antihypertensive agents including thiazide-type diuretics, hydralazine, prazosin, and alpha-methyldopa.

Since TENORMIN is excreted via the kidneys, dosage should be adjusted in cases of severe impairment of renal function. No significant accumulation of TENORMIN occurs until creatinine clearance falls below 35 ml/min/1.73 m^2 (normal range is 100-150 ml/min/1.73 m^2); therefore, the following maximum dosages are recommended for patients with renal impairment:

Creatinine Clearance (ml/min/1.73 m^2)	Atenolol Elimination Half-life (hrs)	Maximum Dosage
15-35	16-27	50 mg daily
<15	>27	50 mg every other day

Patients on hemodialysis should be given 50 mg after each dialysis; this should be done under hospital supervision as marked falls in blood pressure can occur.

HOW SUPPLIED: Tablets of 50 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 105 embossed on the other side are supplied in monthly calendar packages of 28 tablets, bottles of 100 tablets, and unit-dose packages of 100 tablets. Tablets of 100 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 101 embossed on the other side are supplied in bottles of 100 tablets and unit-dose packages of 100 tablets.

Protect from heat, light, and moisture. Store unit-dose and calendar packages at controlled room temperature.

CONGENITAL HEART DISEASE

1469 Accuracy of 2-Dimensional Echocardiographic Diagnosis of Congenitally Bicuspid Aortic Valve: Echocardiographic-Anatomic Correlation in 115 Patients

ROBERT O. BRANDENBURG, Jr., ABDUL J. TAJIK, WILLIAM D. EDWARDS, GUY S. REEDER, CLARENCE SHUB, and JAMES B. SEWARD

In 115 patients under age 50 years who had 2-dimensional (2-D) echocardiographic examinations before aortic valve surgery at the Mayo Clinic, the echocardiograms were reviewed blindly, and the aortic valve structure was categorized as bicuspid, tricuspid, or indeterminate. On the basis of combined surgical and pathologic inspection, 50 aortic valves were congenitally bicuspid, 60 were tricuspid, 4 were unicommissural, and 1 was quadricuspid. By 2-D echocardiography, the number of cusps was indeterminate in 29 patients (25%). When these patients were excluded, the sensitivity, specificity, and diagnostic accuracy of 2-D echocardiography for bicuspid aortic valve were 78, 96, and 93%, respectively. Thus, with adequate 2-D images, echocardiography is a sensitive and highly specific technique for the diagnosis of bicuspid aortic valve.

1474 Classification of the Site of Ventricular Septal Defect by 2-Dimensional Echocardiography

HORACIO CAPELLI, JOSE L. ANDRADE, and JANE SOMERVILLE

Sixty-three patients with ventricular septal defect were investigated with 2-dimensional echocardiography to assess its accuracy in defining the anatomic site of the defect. The defects were classified into subvalvular (subdivided according to which valve the defect is related) and muscular (subdivided according to location in the muscular septum). Echocardiographic findings were compared with the surgical findings in all patients. The method proved reliable in identifying most of the defects and capable of replacing invasive investigation for assessment of uncomplicated ventricular septal defect before surgery.

1481 Results After Repair of Coarctation of the Aorta Beyond Infancy: A 10 to 28 Year Follow-Up With Particular Reference to Late Systemic Hypertension

PATRICIA M. CLARKSON, MICHAEL R. NICHOLSON, BRIAN G. BARRATT-BOYES, JOHN M. NEUTZE, and RALPH M. WHITLOCK

The late outcome in 160 patients aged 1 to 54 years who had surgical repair of coarctation of the aorta was examined 10 to 28 years postoperatively. The minimum duration of follow-up in survivors was 10 years. Twenty years postoperatively the probability of survival of patients discharged from the hospital aged 1 to 19 years at operation was a little less than that of the general population (95% versus 97%). The divergence of death rate from normal was increasingly more marked with increasing age at operation beyond 20 years. Hypertension was more common in patients operated on after age 20 years than in those aged 5 to 19 years at operation ($p = 0.007$). The likelihood of being alive without complications and with a normal blood pressure was 69% at 10 years, 55% at 15 years, and 20% at 25 years postoperatively.

1489 The Valve of the Foramen Ovale in Interatrial Right-to-Left Shunt: Echocardiographic Cineangiocardiographic and Hemodynamic Observations

CHRISTOPH KUPFERSCHMID and DIETER LANG

The valve of the foramen ovale fails to close in patients with postpartum persistent interatrial right-to-left shunt, whether functional or dependent on a cardiac defect. Then it consistently has a marked movement within the cardiac cycle which occasionally can be seen on cineangiocardiography. On M-mode and 2-dimensional echocardiography this movement can be recorded frequently. In 13 patients with cyanotic heart disease and 11 newborns with persistent transatrial right-to-left shunt, the movement of the foramen ovale flap was studied echocardiographically and the findings were compared with those obtained in 20 healthy infants and children. Analysis of interatrial blood pressure differences in 2 patients revealed that the movement of the valve of the foramen ovale reflects interatrial pressure-flow dynamics.

1495 Management of Adults With Congenital Bidirectional Cardiac Shunts, Cyanosis, and Pulmonary Vascular Obstruction: Successful Operative Repair in 3 Patients

VERDI J. DISESA, LAWRENCE H. COHN, and WILLIAM GROSSMAN

Patients with congenital cardiac shunts in whom marked functional disability, cyanosis, and pulmonary hypertension develop have been considered inoperable or at exceedingly high risk. Three adult patients presented with New York Heart Association class IV symptoms, bidirectional shunting with cyanosis, polycythemia, severe pulmonary hypertension, and increased pulmonary vascular resistance. Pulmonary arterial pressure did not decrease in response to administration of 100% oxygen, and 2 patients had lung biopsy results showing advanced pulmonary vascular obstruction. However, in all patients, the net shunt was left-to-right ($Q_p/Q_s > 1$) and the resistance ratio (R_p/R_s) <0.5. All patients survived operation and are now in NYHA class I or II. At repeat cardiac catheterization, pulmonary arterial pressure and resistance had decreased substantially. This high-risk group of patients should still be considered for surgical correction if the usual criteria for operability exist: net left-to-right Q_p/Q_s and $R_p/R_s < 0.50$.

1498 Obstruction Within the Right Ventricular Body: Two-Dimensional Echocardiographic Features

LAURA J. von DOENHOFF and NAVIN C. NANDA

Real-time 2-dimensional echocardiograms were performed in 4 patients, all with considerable obstruction within the body of the right ventricle proven at cardiac catheterization and biplane ventriculography. In 3 patients, the obstruction presented echocardiographically as an "hourglass" narrowing within the right ventricle, and a membranous ventricular septal defect was also present. In the fourth, a patient with hypertrophic cardiomyopathy, the obstruction was seen as a bulging of the septum into the right ventricle. In 3 patients the obstruction was convincingly demonstrated only in the subcostal right ventricular inflow-apex-outflow plane, rather than in the standard echocardiographic planes. Obstruction within the body of the right ventricle is a potentially serious condition which has been overlooked both at cardiac catheterization and at surgery. Demonstration of this lesion by 2-dimensional echocardiography appears feasible and would greatly improve diagnostic accuracy.

1502 Quantitative Analysis of Pulmonary Vascular Disease in Simple Cardiac Anomalies With the Down Syndrome

SHIGEO YAMAKI, TOGO HORIUCHI, and YOSHIHITO SEKINO

Intimal changes and medial thickness of small pulmonary arteries were morphometrically examined in 21 cases of simple cardiac anomalies with the Down syndrome, and their correlations with age and with pulmonary arterial peak pressure were then compared with those of 20 cases of simple cardiac anomalies without the Down syndrome and 17 cases of complete transposition of the great arteries (TGA). Results indicate that (1) intimal changes developed at an earlier age in patients with simple cardiac anomalies and the Down syndrome than in those without the Down syndrome, (2) the intimal changes were more severe than those in simple cardiac anomalies without the Down syndrome at the same level of pulmonary arterial pressure and milder than those in TGA,

Hygroton®
(chlorthalidone USP)

BRIEF SUMMARY

Indications: Hypertension, adjunctive therapy in edema. **Contraindications:** Anuria, hypersensitivity to chlorthalidone or other sulfonamide-derived drugs. **Warnings:** Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. There is a possibility of exacerbation or activation of systemic lupus erythematosus with thiazides, which are related to chlorthalidone. This has not been reported with chlorthalidone. Thiazides cross the placental barrier and appear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in breast milk. If use of the drug is essential, the patient should stop nursing. **Precautions:** Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance. **Adverse Reactions:** Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn. **Usual Dose:** One tablet daily. **How Supplied:** Tablets—100 mg. (white, scored), 50 mg. (aqua) in bottles of 100, 1000 and 5000; 25 mg. (peach) in bottles of 100 and 1000; unit-dose blister packs, boxes of 100 (10 x 10 strips).

and (3) the media of small pulmonary arteries in simple cardiac anomalies with the Down syndrome was thinner than the media in cases without the syndrome at the same radius and the same level of pulmonary arterial pressure but thicker than the media in TGA.

1507 Two-Dimensional Echocardiographic Recognition of the Right Aortic Arch

VINCENZO CELANO, DANIEL R. PIERONI, ROBERT L. GINGELL, and J-MICHEL A. ROLAND

A mirror image right aortic arch (RAA) is frequently associated with congenital heart disease. While 2-dimensional (2-D) echocardiography has been used to elucidate the left aortic arch (LAA), detailed description of the technique for RAA has not been reported. This study was pursued to delineate the 2-D echocardiographic approach to the patient with RAA. There were 27 patients with LAA (Group A) and 27 with RAA (Group B) in this study. The standard suprasternal long axis correctly identified the LAA in all Group A patients, but in Group B it located only the ascending aorta. This simulated an interrupted aortic arch anomaly. Transducer realignment to position 2 confirmed RAA in all Group B patients. In the parasternal axes the left descending aorta was detected posterior to the atrioventricular groove or left ventricle in every Group A patient but in none in Group B. The descending aorta was found to the left of the spine on the abdominal short-axis view in both groups. The 2-D echocardiographic technique proposed for RAA is simple, rapid, and definitive. It should be pursued whenever LAA cannot be demonstrated, especially in children in whom a congenital heart defect is suspected. Anticipation of RAA can be used to expedite chest and cardiovascular surgery.

SYMPOSIUM ON RESULTS OF THE MUSTARD OPERATION FOR COMPLETE TRANSPOSITION OF THE GREAT ARTERIES

JAMES R. ZUBERBUHLER, Guest Editor

1513 Introduction

JAMES R. ZUBERBUHLER

1514 Hemodynamic Function After the Mustard Operation for Transposition of the Great Arteries

SANG C. PARK, WILLIAM H. NECHES, ROBERT A. MATHEWS, FREDERICK J. FRICKER, LEE B. BEERMAN, DONALD R. FISCHER, CORA C. LENOX, and JAMES R. ZUBERBUHLER

Pre- and postoperative cardiac catheterization data and cineangiograms were reviewed in 82 patients surviving the Mustard operation for transposition of the great arteries. Forty-six (56%) had no or insignificant associated cardiac lesions, while the remaining 36 had a ventricular septal defect, pulmonic stenosis, or both, requiring surgical intervention at the time of operation. Significant systemic venous obstruction occurred in 11 patients (13%), and 6 of these 11 required reoperation. Superior vena caval obstruction was well tolerated in most patients, even when there was high pressure in the superior vena cava. Pulmonary venous obstruction was a less common complication, occurring in 5 patients. Tricuspid regurgitation was uncommon but occurred more often in patients who had transatrial closure of a ventricular septal defect. Left ventricular outflow obstruction was common (38%) preoperatively. The obstruction was relieved surgically in 12 patients, and 6 of these patients with localized obstruction had a good result. However, the gradient was not adequately relieved in patients with diffuse obstruction. Mild to moderate left ventricular outflow gradients regressed spontaneously in most patients after the Mustard operation.

1520 Rest and Exercise Right and Left Ventricular Function Late After the Mustard Operation: Assessment by Radionuclide Ventriculography

JUDITH H. MURPHY, MARTHA M. BARLAI-KOVACH, ROBERT A. MATHEWS, LEE B. BEERMAN, SANG C. PARK, WILLIAM H. NECHES, and JAMES R. ZUBERBUHLER

Rest and exercise radionuclide ventriculography was performed in 26 asymptomatic patients with transposition of the great arteries a mean of 9.3 years after they underwent the Mustard operation. The mean resting right (systemic) ventricular ejection fraction (RVEF) was 0.50 ± 0.10 (±1 standard deviation). With exercise the RVEF increased in 9 patients and either failed to increase or decreased in 15. The weight-adjusted work load performed

was a first predictor of right ventricular exercise response; patients whose RVEF increased did more work. The mean resting left (pulmonic) ventricular ejection fraction (LVEF) was 0.58 ± 0.09. With exercise LVEF increased in 14 patients and failed to increase in 10. The presence of complex ventricular arrhythmia documented on Holter monitoring was a first predictor of failure of the LVEF to increase with exercise. No other factors were predictive of the rest or exercise ejection fraction of either ventricle.

26 Exercise Studies After the Mustard Operation in Transposition of the Great Arteries

ROBERT A. MATHEWS, FREDERICK J. FRICKER, LEE B. BEERMAN, ROBERT J. STEPHENSON, DONALD R. FISCHER, WILLIAM H. NECHES, SANG C. PARK, CORA C. LENOX, and JAMES R. ZUBERBUHLER

Twenty-one postoperative patients with transposition of the great arteries (TGA) underwent graded exercise testing 4 to 15 years (mean 9) after the Mustard operation. No patients had subject exercise intolerance before testing, although some had symptomatic resting arrhythmias. Correlations were made between cardiac catheterization data and 24-hour ambulatory monitoring. Exercise tolerance was diminished in nearly half of the patients. No statistically significant differences were found in heart rate or blood pressure responses, but maximal oxygen consumption values were lower than the control values ($p < 0.001$) in the larger patients. Arrhythmias were present or provoked in most patients during exercise testing. Only 28% remained in normal sinus rhythm during and after exercise. Multifocal premature contractions were the most serious arrhythmias demonstrated. Some long-term survivors of the Mustard operation may have abnormal exercise dynamics, even though they may be asymptomatic and have normal physical activities and endurance. Mean maximal systolic blood pressure, heart rate, oxygen consumption, and maximal treadmill times were consistently in the low-normal range or were statistically lower than normal.

0 Arrhythmias in Transposition of the Great Arteries After the Mustard Operation

LEE B. BEERMAN, WILLIAM H. NECHES, FREDERICK J. FRICKER, ROBERT A. MATHEWS, DONALD R. FISCHER, SANG C. PARK, CORA C. LENOX, and JAMES R. ZUBERBUHLER

The purpose of this study was to provide a systematic evaluation of the electrophysiologic function of 87 survivors of the Mustard operation at a single institution. The review of the surface electrocardiograms showed normal sinus rhythm in 52%, sinus node dysfunction in 27%, and atrioventricular block in 16%. Holter monitoring was performed in an unselected subgroup of 26 patients. Sinus node dysfunction was found in 58%, atrioventricular block in 27%, ventricular ectopy in 50%, and supraventricular ectopy in 27%, and only 8% had no abnormalities present. Intracardiac electrophysiologic evaluation showed a high incidence of abnormal sinus node recovery times and suboptimal response of the atrioventricular conduction system to rapid atrial pacing. When all the modalities used in this study were considered, sinus node dysfunction occurred in 47% of patients, ectopy in 34%, and atrioventricular block in 23%. Although only 30% of the group had no evidence of dysrhythmias, symptoms from rhythm or conduction disturbances were uncommon.

Summary

JAMES R. ZUBERBUHLER

VALVULAR HEART DISEASE

Trial of Combined Warfarin Plus Dipyridamole or Aspirin Therapy in Prosthetic Heart Valve Replacement: Danger of Aspirin Compared With Dipyridamole

JAMES H. CHESEBRO, VALENTIN FUSTER, LILA R. ELVEBACK, DWIGHT C. McGOON, JAMES R. PLUTH, FRANCISCO J. PUGA, ROBERT B. WALLACE, GORDON K. DANIELSON, THOMAS A. ORSZULAK, JEFFREY M. PIEHLER, and HARTZELL V. SCHAFF

The incidence of thromboembolism in patients with prosthetic heart valves increases directly with time after operation. Patients with 1 or more mechanical prosthetic heart valves were randomized to therapy with warfarin plus dipyridamole (400 mg/day) or warfarin plus aspirin (500 mg/day) and followed with a concurrent nonrandomized control group taking warfarin alone. In 534 patients followed up 1,319 patient-years, excessive bleed-

Continued on Page A23

ing requiring blood transfusion, or hospitalization occurred in more patients on warfarin plus aspirin (23 of 170 [14%], or 6.0/100 patient-years) than in patients on warfarin plus dipyridamole (7 of 181 [4%], or 1.6/100 patient years, $p < 0.001$) or warfarin alone (9 or 183 [5%], or 1.8, $p < 0.001$). A trend toward reduction in thromboembolism was present in the warfarin plus dipyridamole group (2 of 181 [1%], or 0.5/100 patient-years) compared with warfarin plus aspirin (7 of 170, 4%, or 1.8/100 patient-years) or warfarin alone (6 of 183, 4%, or 1.2/100 patient-years). Warfarin plus aspirin resulted in excessive bleeding and is contraindicated. Continued follow-up is in progress for the detection of thromboembolism.

1542 Early Detection of Left Ventricular Dysfunction in Chronic Aortic Regurgitation as Assessed by Contrast Angiography, Echocardiography, and Rest and Exercise Scintigraphy

ROBERT L. HUXLEY, ANDREW GAFFNEY, JAMES R. CORBETT, BRIAN G. FIRTH, RONALD PESHOCK, PASCAL NICOD, JAMES S. RELLAS, GEORGE CURRY, SAMUEL E. LEWIS, and JAMES T. WILLERSON

The best method for detecting early left ventricular (LV) dysfunction in patients with chronic aortic regurgitation (AR) is uncertain. Variables used previously to identify dysfunction have included (1) angiographic methods to identify an LV end-systolic volume index (LVESVI) ≥ 60 ml/m^2, (2) echocardiographic measurements to identify LV end-systolic dimension (LVESD) ≥ 5.5 cm or LV fractional shortening $\leq 25\%$, and (3) a depressed LV ejection fraction (EF) at rest and/or an LVEF or LVESVI that deteriorates with exercise as detected by myocardial scintigraphic measurements. In the present study, 15 consecutive asymptomatic or only mildly symptomatic patients with isolated 2+ to 4+ AR underwent (1) rest and exercise gated radionuclide ventriculography, (2) M-mode echocardiography, and (3) LV angiography. No other cause of LV dysfunction was apparent in 13 patients; 1 patient had moderate systemic arterial hypertension and 1 had 50% luminal diameter narrowing of the proximal left anterior descending coronary artery. Ten patients had abnormal LV function during exercise as evidenced by radionuclide ventriculography. However, only 4 of the 10 patients with exercise-induced LV dysfunction had an angiographic left ventricular end-systolic index ≥ 60 ml/m^2, and only 1 had an echocardiographically determined LVESD ≥ 5.5 cm. Thus (1) exercise radionuclide ventriculography identifies LV dysfunction earlier than traditionally used measurements, (2) LV dysfunction appears to persist in patients who manifest it and develop in others who did not have it originally, and (3) echocardiographic dilatation of the LVESD to ≥ 5.5 cm appears to be a late and relatively unusual occurrence.

1551 Effect of Elevating the Wrist on the Radial Pulse in Aortic Regurgitation: Corrigan Revisited

CAROLE A. WARNES, PETER C. HARRIS, and HARRY W. FRITTS

In 5 patients with severe aortic regurgitation (AR), the intraarterial radial pulse was recorded simultaneously with the external radial artery deflection of the other wrist. Recordings were made with the arms horizontal and repeated after elevation of the wrists, until the arms were vertical. Elevating the arm of a patient with AR increased the pulsation recorded over the radial artery, lowered the mean intraarterial pressure, and reduced the pulse pressure. The results suggest that elevation increases the compliance of the arterial wall, primarily by moving the artery to a lower position on its pressure-volume curve. The same changes occurred in 5 normal subjects but were less pronounced.

THERAPY

1554 Effects of Disopyramide on Left Ventricular Function: Assessment by Radionuclide Cineangiography

JOHN GOTTDIENER, ROBERT DIBIANCO, RICHARD BATES, BERTRAM J. SAUBERBRUNN, and ROSS D. FLETCHER, *With the technical assistance of* ROD NOSS and ANN RUSK

Disopyramide, although an effective antiarrhythmic drug, has been associated with congestive heart failure. Therefore, radionuclide cineangiography was performed at rest and during exercise stress to determine the effects of disopyramide on left ventricular function in patients with coronary artery disease and idiopathic dilated cardiomyopathy. An oral loading dose of 300 mg (serum level 3.6 ± 1.3 μg/ml) produced significant decreases in ejection fraction at rest and during exercise in most patients, whereas a smaller maintenance dose of 150 mg 4 times daily did not. Such "loading" regimens or any chronic drug regimen associated with similarly high, albeit "therapeutic" drug levels should be monitored closely.

We at MSD feel it is appropriate to bring you t
of cardioprotective since it was MSD that brou
the impressive clinical data[1] that documented t
benefits of BLOCADREN® (Timolol Maleate, MS
stabilized patients who have survived
the acute phase of a myocardial infarction.

[1]The Norwegian Multicenter Study Group: Timolol-induced reduct
and reinfarction in patients surviving acute myocardial infarction,
304(14):801-807, April 2, 1981.

BLOCADREN is contraindicated in patients with bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated.

In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure.

(TIMOLOL MALEATE) MSD

CONTRAINDICATIONS:

Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: *Impaired Hepatic or Renal Function*: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy—Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n=176) %	Placebo (n=168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
INTEGUMENTARY		
pruritus	1.1	0
NERVOUS SYSTEM		
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction†		Withdrawal‡	
	Timolol (n=945) %	Placebo (n=939) %	Timolol (n=945) %	Placebo (n=939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure—Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema—Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1
AV Block 2nd or 3rd degree	<1	<1	<1	<1
Sinoatrial Block	<1	<1	<1	<1
Cold Hands and Feet	8	<1	<1	0
Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

†When an adverse reaction recurred in a patient, it is listed only once.

‡Only principal reason for withdrawal in each patient is listed.

These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole*: extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular*: cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness; *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes; *Urogenital*: impotence, urination difficulties.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS); *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

Now more convenient than ever in once-a-day dosage

Lopressor®
metoprolol tartrate

An antihypertensive beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Prescribing Information

Brief Summary of Prescribing Information.

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings *Cardiac Failure:* Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions *Impaired Hepatic or Renal Function:* The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

Accuracy of 2-Dimensional Echocardiographic Diagnosis of Congenitally Bicuspid Aortic Valve: Echocardiographic-Anatomic Correlation in 115 Patients

ROBERT O. BRANDENBURG, Jr., MD, ABDUL J. TAJIK, MD, WILLIAM D. EDWARDS, MD, GUY S. REEDER, MD, CLARENCE SHUB, MD, and JAMES B. SEWARD, MD

The preoperative 2-dimensional (2-D) echocardiograms of all patients <50 years of age in whom the aortic valve had been directly inspected by the surgeon or the pathologist or both were reviewed. From June 1977 to June 1981, 283 patients aged ≤50 years had aortic valve surgery at the Mayo Clinic: 115 (aged 1 to 50 years [mean 32]) had 2-D examinations preoperatively. The echocardiograms were reviewed blindly, and the aortic valve structure was categorized as bicuspid, tricuspid, or indeterminate. On the basis of combined surgical and pathologic inspection, 50 aortic valves were c genitally bicuspid, 60 were tricuspid, 4 were commissural, and 1 was quadricuspid. By echocardiography, the number of cusps was in terminate in 29 patients (25%). When these patie were excluded, the sensitivity, specificity, and agnostic accuracy of 2-D echocardiography for cuspid aortic valve were 78, 96, and 93%, resp tively. Thus, with adequate 2-D images, echoc diography is a sensitive and highly specific te nique for the diagnosis of bicuspid aortic valve

Bicuspid aortic valve is one of the most common congenital cardiac anomalies, occurring in 0.4 to 2% of all births. The most common complication is acquired stenosis due to calcification, with increased cuspid rigidity.[1,2] Infective endocarditis is a common cause of death in patients older than 20 years with bicuspid valve[3] and is potentially preventable with antibiotic prophylaxis. Because the complications of congenitally bicuspid aortic valve are potentially so devastating, its early identification is important. Although 2-dimensional (2-D) echocardiography has been used in the noninvasive diagnosis of bicuspid aortic valve, the agnostic accuracy of this technique is not establis This study determines the sensitivity, specificity, predictive accuracy of 2-D echocardiography in th agnosis of congenitally bicuspid aortic valve.

From the Mayo Clinic and Mayo Foundation, Rochester, Minnesota.
Address for reprints: Abdul J. Tajik, MD, Mayo Clinic, 200 First Street SW, Rochester, Minnesota 55905. Manuscript received July 27, 1982; revised manuscript received January 27, 1983, accepted January 28, 1983.

Methods

Selection of patients: From June 1977 to June 1981 patients aged ≤50 years were operated on for aortic ste or aortic regurgitation. Preoperative 2-D echocardiogra examinations were performed in 115 of the 283 patients (4 These 115 patients form the basis of this retrospe study.

Patient population: There were 83 male and 32 fe patients aged 2 months to 50 years (mean 32 years). Tw patients had aortic valvotomy, and the remaining 103 pat had valve replacement. On clinical examination, 53 pat had isolated aortic regurgitation, 32 had isolated aortic

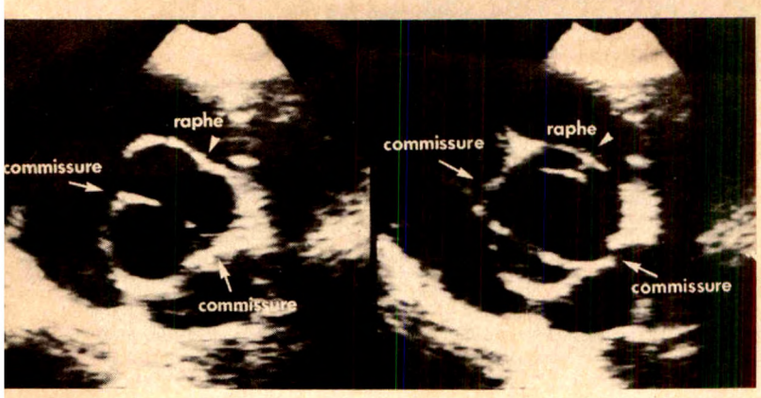

FIGURE 1. Parasternal short-axis view of a bicuspid aortic valve in diastole (**left**) and systole (**right**). Commissures are abnormally located at 4 o'clock and nearly 10 o'clock, with a raphe at 1 o'clock (**arrowhead**). Study of the valve's opening and closing pattern allows distinction of 2 rather than 3 cusps.

nosis, and 30 had combined aortic stenosis and aortic regurgitation. Seven patients had ascending aortic aneurysms (4 with Marfan's syndrome), and aortic dissections were present in 4 patients (2 with Marfan's syndrome). Seventeen patients (mean age 26 years; range 13 to 50) had a history of infective endocarditis: 15 of them had isolated aortic regurgitation, and 2 had combined aortic regurgitation and aortic stenosis.

Echocardiographic examination: *M-mode:* M-mode echocardiograms were obtained in 84 (73%) of 115 patients and were reviewed blindly to determine the eccentricity index. Eccentricity index of the diastolic aortic valve echoes was calculated according to the following formula: EI = 0.5 × A/a, where EI = eccentricity index, A = aortic root diameter at the onset of diastole, and a = distance from diastolic aortic closure to the nearest aortic wall at the onset of diastole.

Two-dimensional: Detailed 2-D echocardiographic examinations by a technique previously reported[4] were performed with a commercially available wide-angle phased-array or mechanical sector scanner (2.25-, 3-, or 5-MHz transducer). The images were permanently recorded on a 3/4-inch videotape for future analysis. Still frames of the sector scans published in this article were photographed by a 35-mm camera

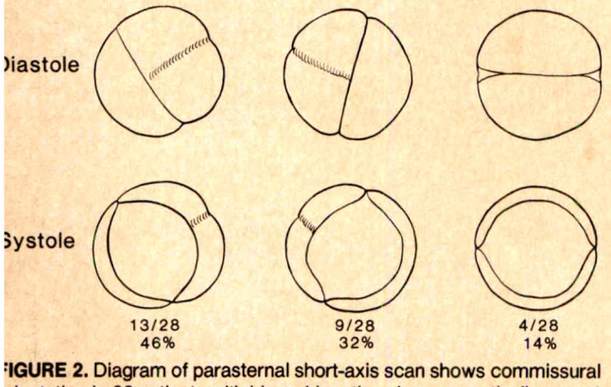

FIGURE 2. Diagram of parasternal short-axis scan shows commissural orientation in 28 patients with bicuspid aortic valves correctly diagnosed by 2-D echocardiography. Orientation of commissures was indeterminate in 2 patients. The most common pattern (**left pair**) demonstrated posterior commissure at the 4 or 5 o'clock position and anterior commissure at the 9 or 10 o'clock position, with raphe (when visualized) at the 1 or 2 o'clock position. This pattern resulted in a larger anterior and slightly smaller posterior cusp. In the next most common pattern (**middle pair**), anterior commissure was at the 1 or 2 o'clock position and posterior commissure usually at the 6 o'clock position, with raphe (when visualized) at the 9 or 10 o'clock position. This pattern usually resulted in a larger right than left cusp. Least frequently visualized (**right pair**) were commissures at the 3 and 9 o'clock positions (no raphe) resulting in equal-sized anterior and posterior cusps.

assembly. A satisfactory 2-D echocardiographic parasternal short-axis view was required to determine the number of aortic valve cusps with transducer angulation such that the aortic root appeared circular and not elliptical. Inaccurate angulation causes an oblique cut that makes valve cusps of equal size appear unequal and eccentric.

The 2-D echocardiographic examinations of the aortic valve in the long and, particularly, the short axes were reviewed blindly by 2 of us without knowledge of clinical information or surgical findings. Review of the videotapes was supplemented by the use of stop-frame and slow-motion analysis to enhance definition of rapidly moving cusps. In diastole, the normal aortic cusp margins form a Y pattern, with commissures at 2, 6, and 10 o'clock. Aortic valve commissures seen at other than these locations strongly suggested the presence of an anatomically abnormal and possibly bicuspid valve. Figure 1 shows a bicuspid valve with commissures at 4 and 10 o'clock and a raphe at 1 o'clock. We found 3 types of commissural orientation in bicuspid valves (Fig. 2). Special attention was also paid to the opening motion of the aortic cusps during systole, because this feature enhanced further the differentiation of a bicuspid from a tricuspid aortic valve (Fig. 3). On the basis of the foregoing criteria, the aortic valve was judged tricuspid, bicuspid, or indeterminate.

Surgical examination: A surgical description of the number of aortic valve cusps was available in 105 of the 115 patients (91%) but not in the remaining 10 patients. After excision, the valves were submitted for pathologic evaluation.

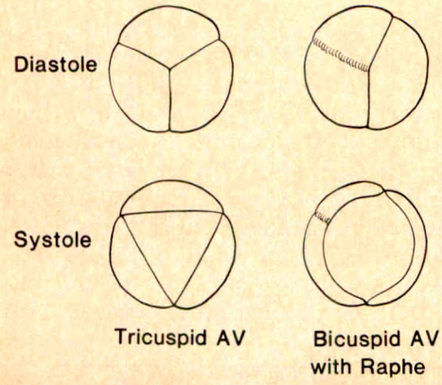

FIGURE 3. Diagram of parasternal short-axis scan of tricuspid (**left**) and bicuspid (**right**) aortic valves (AV) in diastole (**top**) and systole (**bottom**). Although diastolic appearance of both valves may be similar, viewing the opening pattern distinguishes a raphe from a commissure.

TABLE I Two-Dimensional Echocardiography in Aortic Valve Disease: Diagnosis in 115 Patients

Aortic Valve Structure	Patients	
	n	%
Bicuspid	31	27
Tricuspid	55	48
Indeterminate	29	25
Calcified valve	14	. . .
Inadequate visualization	15	. . .

Morphologic examination: Of the 103 aortic valves surgically excised at the time of aortic valve replacement, 10 from patients with a history of infective endocarditis were submitted for bacteriologic culture. Four valves were unavailable for pathologic examination, and 3 others were submitted in fragments, so that the number of cusps could not be determined. Therefore, pathologic analysis of the aortic valve was possible in 86 patients. In the remaining 29 patients, the number of aortic valve cusps was based solely on the surgeon's description. Anatomic correlation by surgical description or pathologic examination, or both, was available in all patients.

Results

Surgical-pathologic diagnosis: On the basis of combined surgical-pathologic evaluation, there were 50 congenitally bicuspid and 60 tricuspid aortic valves. Four patients had unicommissural valves, and 1 patient had a quadricuspid valve. Of the 86 valves examined pathologically, 82 had a surgical description available. Disagreement between surgical and pathologic diagnoses was noted in 6 patients (7%), and in all 6, a congenitally bicuspid valve (pathologic diagnosis) was called tricuspid by the surgeon. In these cases, the pathologic diagnosis was considered to be correct. Three unicommissural valves were diagnosed as bicuspid by the surgeon. The quadricuspid valve was correctly diagnosed at surgery. As noted, 29 valves had only a surgical description without pathologic confirmation.

Two-dimensional echocardiographic diagnosis: The number of aortic valve cusps could be determined by 2-D echocardiography in 86 patients (75%). Cusp number was indeterminate in the remaining 29 patients (25%)—in 15 (13%) because of inadequate echocardiographic imaging and in 14 (11%) because of extensive valvular calcification (Table I). Echocardiographic images were defined as inadequate when commissural margins and cuspid motion were indistinct without excessive valvular calcification or the tomographic section of aorta was not circular-appearing.

TABLE II Correlation Between Surgical-Pathologic Diagnosis and 2-D Echocardiographic Diagnosis in 85 Patients

Aortic Valve Structure by 2-D Echocardiography	Surgical-Pathologic Diagnosis of Aortic Valve Cusp Number	
	Bicuspid	Tricuspid
Bicuspid	28	2
Tricuspid	8	47
Diagnostic accuracy for		
Bicuspid valve	93%	
Tricuspid valve	85%	
Sensitivity	78%	
Specificity	96%	

Correlations between the surgical-pathologic and 2-D echocardiographic diagnoses were made after the 29 patients with indeterminate studies were excluded. A 2-D echocardiographic diagnosis of bicuspid aortic valve was made in 30 patients and was correct in 28 (93% diagnostic accuracy). Of 55 tricuspid valves, 47 were correctly diagnosed (85% diagnostic accuracy). Of the 36 bicuspid aortic valves (by surgical-pathologic examination), 28 were correctly diagnosed by 2-D echocardiography (78% sensitivity). Of 49 tricuspid valves (surgical-pathologic examination), 47 were correctly diagnosed by echocardiography (96% specificity) (Table II).

In 26 of the 28 patients with bicuspid aortic valves who had a correct 2-D echocardiographic diagnosis, the orientation of commissures was visualized (Fig. 2). Raphes were identified in 20 patients.

The accuracy of 2-D echocardiography in the diagnosis of a bicuspid aortic valve was not related to age of the patient, although the small numbers involved made analysis difficult (Table III). Both patients with tricuspid aortic valves and false-positive 2-D echocar-

TABLE III Accuracy of 2-D Echocardiographic Diagnosis Related to Age in 101 Patients*

Age (yr)	2-D Echocardiographic Diagnosis							
	Correct		Incorrect		Inadequate			
					Calcified		Incomplete	
	Tri	Bi	Tri	Bi	Tri	Bi	Tri	Bi
0–9	1	3	0	1	0	0	0	1
10–19	5	7	2	2	0	0	0	2
20–29	8	0	0	1	0	0	2	1
30–39	11	4	0	1	1	1	2	1
40–50	21	5	0	3	4	6	3	2

* Quadricuspid valve not included.
Bi = bicuspid aortic valve; Tri = tricuspid aortic valve.

TABLE IV Accuracy of 2-D Echocardiographic Diagnosis in 63 Patients With Aortic Regurgitation or Aortic Stenosis

2-D Echocardiographic Diagnosis	Surgical-Pathologic Diagnosis	
	Bicuspid	Tricuspid
Aortic regurgitation		
Bicuspid	11	1
Tricuspid	2	29
Aortic stenosis		
Bicuspid	10	1
Tricuspid	5	4

	Insufficiency (%)	Stenosis (%)
Indeterminate study	17	31
Sensitivity	85	67
Specificity	97	80

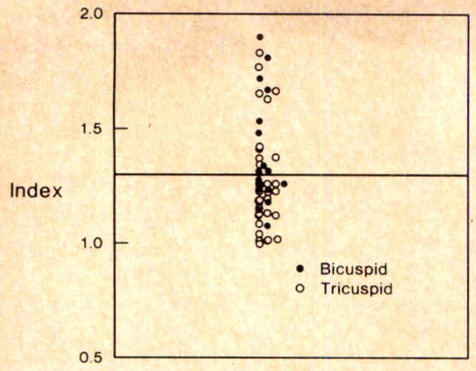

FIGURE 4. Preoperative M-mode eccentricity indexes in 54 patients. Horizontal line is drawn at eccentricity index 1.3.

diographic diagnoses of bicuspid aortic valve were young (aged 19 and 13). Pathologic confirmation was not available because both patients underwent aortic valvotomy.

Analysis of 2-D echocardiographic diagnostic accuracy related to the patient's functional lesion is shown in Table IV. Although the finding was not statistically significant, patients with aortic regurgitation had a correct diagnosis more often than did patients with isolated aortic stenosis (sensitivity 85 and 67%, respectively) ($p = 0.40$). The specificity for the diagnosis of tricuspid aortic valve was also higher in patients with aortic regurgitation than in those with aortic stenosis (specificity 97 and 80%, respectively) ($p = 0.27$). In addition, 9 of 29 patients (31%) with aortic stenosis had inadequate studies compared with 9 of 52 patients (17%) with aortic regurgitation ($p = 0.17$). These differences were not statistically significant, possibly because of the small number of patients involved. The mean ages of the 2 groups were similar at 32 and 26 years, respectively ($p = 0.14$; not significant).

M-mode eccentricity index: Preoperative M-mode echocardiographic eccentricity indexes were determined in 54 of the 84 patients (64%). No eccentricity index was calculable in the remaining 30 patients because of multiple diastolic echoes in 20 and an inadequate echo of the aortic valve or aortic root in 10. A wide scatter of values was demonstrated (Fig. 4). With an eccentricity index of 1.3, the sensitivity and specificity for the bicuspid aortic valve were 55 and 71%, respectively.

Infective endocarditis: Of the 17 patients with history of infective endocarditis, 11 had tricuspid valves and 6 had bicuspid valves. Five of the 6 bicuspid valves were correctly diagnosed by 2-D echocardiography, and 1 was incorrectly diagnosed as tricuspid. Vegetations were diagnosed on 4 of the 6 bicuspid valves by 2-D echocardiography and later were confirmed at surgery in all cases. In the remaining 2 patients, no vegetations were seen on echocardiographic or surgical examination. Eight of the 11 tricuspid valves were correctly diagnosed by 2-D echocardiography, 2 were indeterminate, and one was mistakenly diagnosed as bicuspid. Vegetations were visualized on 2-D echocardiography on both indeterminate tricuspid valves and on 2 others, and all 4 were surgically confirmed. No false-positive diagnoses of vegetations occurred in either bicuspid or tricuspid valves.

Discussion

Normal aortic valves are tricuspid, with 3 near-equal-sized cusps. Various congenital abnormalities can occur, including tricuspid valves with significant unequal cusp size,[5] quadricuspid valves,[6] unicommissural valves,[7,8] and bicuspid valves.[2,3] Bicuspid valves may have 3 unequal aortic sinuses and a tall raphe along the conjoined cusp or only 2 aortic sinuses and a shallow raphe. These anatomic variations of bicuspid aortic valves can be visualized by 2-D echocardiographic techniques. Earlier claims of high sensitivity and specificity in the diagnosis of a bicuspid aortic valve with M-mode echocardiography have been challenged. Use of the maximal eccentricity index is limited because of various results depending on transducer angulation. Nanda et al[11] found that 10 patients with known bicuspid aortic valves had symmetric closure of cusps that depended on transducer angulation and also a change in cardiac cycle. Our eccentricity index data showed a wide range of results, with relatively low sensitivity and specificity for this technique in the diagnosis of bicuspid aortic valve.

A 2-D echocardiographic short-axis view of the aortic valve is a prerequisite for determination of the number of aortic cusps. Care should be taken that this tom

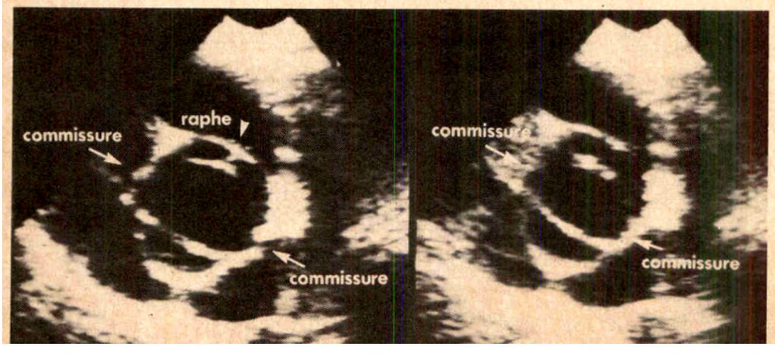

FIGURE 5. Parasternal short-axis views of bicuspid aortic valve in systole. **Left,** raphe is visible at approximately 1 o'clock. **Right,** scanning at a slightly more cephal

graphic section is perpendicular (aorta appearing circular) and not oblique. The tricuspid aortic valve has commissures at the 2, 6, and 10 o'clock positions, resulting in a letter Y configuration during diastole and an "inverted triangle" appearance in systole. In a bicuspid aortic valve, the commissures are usually at the 4 and 10 o'clock or 1 and 6 o'clock positions, and the cusps assume a fish-mouth appearance during systole. The results of the orientation of the commissures in our study were comparable to those of a previous pathologic study of 50 bicuspid valves.[12] The raphe was more or less perpendicular to the commissural orientation. Differentiation between a tricuspid valve with a true commissure and a bicuspid valve with a raphe is occasionally difficult, because the diastolic configuration can be similar. Study of the opening and closing pattern of the valve usually allows differentiation between the triangular-shaped tricuspid orifice and the characteristic fish-mouth–appearing bicuspid valve (Fig. 3). In addition, because most raphes are shallow and stop well below the cuspid line of closure, short-axis scanning above the valve produces "dropout" of the raphe and clearer visualization of the bicuspid nature of the valve (Fig. 5). Evaluation of cuspid motion is greatly facilitated by use of slow motion and stop frame.

When adequate images were available, we found that 2-D echocardiography was a sensitive and highly specific noninvasive method in the detection of bicuspid aortic valves. The specificity was especially remarkable, only 2 of 49 tricuspid valves being mistakenly diagnosed as bicuspid. Pathologic examination was not available for either of these valves. Determination of the number of aortic cusps was limited by either inadequate visualization of the cusps or dense valvular calcification, which prevented a diagnosis in 29 of the 115 patients (25%). This figure is comparable to that in previous studies of the feasibility of visualizing the aortic valve.[13] Adequate visualization of the valve was better in younger patients, because only 13% of patients aged ≤ years had indeterminate examinations.

The most useful application of this technique is in t evaluation of the asymptomatic patient in whom outflow systolic ejection murmur, a short aortic diasto murmur, or an ejection click (1 or more of these sign makes the clinician suspect bicuspid aortic valv Confident diagnosis of bicuspid aortic valve by 2 echocardiography in such a patient is clinically impo tant because it identifies a subset of patients who a at high risk for future complications.
